
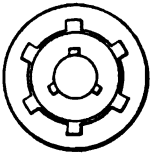

FIG. 179. — Leblanc-Scherbius phase advancer without windings on stator.

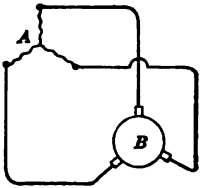

FIG. 180. — Diagrammatic representation of Scherbius statorless phase advancer.

sufficient to complete the magnetic circuit and that no stator is necessary. Consequently in a considerable number of his smaller sizes of phase advancers Scherbius has abandoned the use of a stator and has built his phase advancers without any air space in the magnetic circuit. The consequent reduction in the magnetic reluctance permits at small loads the generation of an increased e.m.f. of rotation and results in a greater improvement of the power-factor at light loads.

**326. Operating data of Scherbius phase advancers.** In Fig. 181 are given curves, showing the power-factor obtained by Scherbius on a

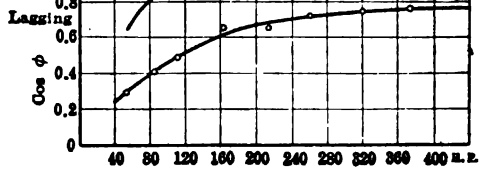

FIG. 181.—Performance curves of a 400-h.p. motor when operated respectively with (upper curve) and without (lower curve) a Scherbius phase advancer.

400-h.p. motor when operated respectively with and without a phase advancer. It is seen from the curves that at only 20 per cent. of rated load the power-factor is improved from 0.4 to 0.8, and that beyond half load the current is leading. The 400-h.p. motor on which the tests were made, has 24 poles and runs from a 3,300-volt, 32-cycle circuit at 160 rev. per min. The overall dimensions of the advancer (including a small motor to drive it) are 50 in. × 22 in. × 25 in., and the weight of the advancer and its driving

Digitized by Google

motor amounts to 0.34 metric ton. This particular phase advancer was fitted with a stator but without any windings. The general tendency is toward the employment of a stator fitted with compensating windings but without any exciting windings. § At page 366 of Vol. L, of the *Journ.* I. E. E. are given curves, reproduced in Fig. 182, showing the improvement effected in a 25-h.p., 50-cycle, 450-volt, 1,000-rev. per min., three-phase induction motor by fitting a Scherbius phase advancer on the end of the shaft of its rotor. In the motor the stator is the secondary and its three terminals are connected to three brushes on the commutator of the advancer. The total weight of the motor and advancer is only 0.36 metric ton, or 14.5 kg. per h.p.

At a steel mill in Sheffield in England, a Scherbius advancer with a stator fitted exclusively with compensating windings is employed in the rotor circuit of a 700-h.p. induction motor which is usually running lightly loaded. Without the phase advancer the power-factor of the system is 0.55. With the advancer it is increased to 0.7. The advancer is driven by a 2-h.p. induction motor running at nearly 1,500 rev. per min.

**327. The Kapp vibrator.** In *Eclairage Electrique*, for August 5, 1899, Leblanc suggested that phase control could be accomplished by the use of a device which he termed a "recuperator" and which consisted of a copper disc through which alternating current was transmitted radially between the centre and the periphery, and which was located in a magnetic

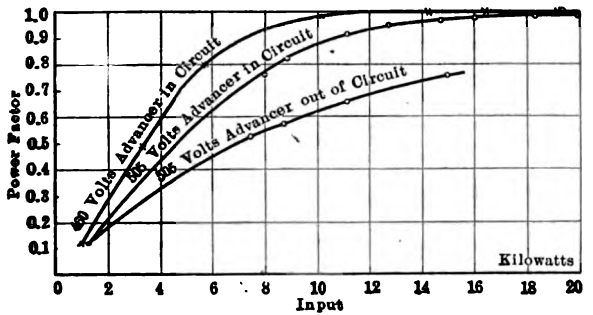

FIG. 182.—Performance curves of a 25-h.p. motor when operated respectively with and without a Scherbius phase advancer.

field in which it oscillated. The current was transmitted to and from the disc by means of a slip-ring on the shaft and a trough of mercury in which the disc dipped.

Dr. Gisbert Kapp has developed from this principle a commercial phase advancer which he terms a "vibrator." Kapp has realised that success is contingent upon employing as a vibrating element a rotor of small diameter. He conveys the current into the rotor windings by brushes bearing on a commutator. In order that the commutator may be small and cheap, it is desirable that the secondary of the main motor shall be wound for a fairly high pressure and small current. The scheme is illustrated in Fig. 183 taken from an article by Kapp published in "The Electrician" for May 17 and 24, 1912, pp. 222 to 272. *VVV* are three vibrating armatures for improving the power-factor of a three-phase motor whose rotor has a three-phase winding. A three-phase motor can, as well, have a two-phase rotor, and this will permit of reducing the number of vibrating armatures from three to two. A starting resistance, *S*, of the usual type is provided. It is short-circuited after the motor has acquired speed. The field of the vibrator is shown excited from a battery, but any convenient source of direct current may be employed. Dr. Kapp states that the power required for excitation is only a fraction of 1 per cent. of the power of the motor, and that the loss of power by windage and brush resistance in the armatures is of the same

Digitized by Google

order of magnitude. A switch may be arranged to short-circuit the vibrator while the motor is being started and thus avoid subjecting the windings of the vibrating armatures to the high pressure established, during starting, in the rotor of the induction motor. When it is arranged to protect the vibrator in this way, its armature need only be provided with low-voltage insulation, since the pressure of the rotor windings during normal running is only a small percentage of the pressure during starting.

There is no difficulty in proportioning a vibrator for good commutation. At maximum speed the current is zero and at maximum current the speed is zero. Consequently at both these limits the reactance voltage is zero. The reactance voltage passes through its maximum value at some intermediate value of speed and current, but there is no difficulty in so proportioning the vibrator that this maximum value of the reactance voltage will be low. In Vol. LI (1913) of the *Journ.* I. E. E., are given, p. 292 the curves reproduced in Fig. 184. These curves were obtained on a 40.8-cycle, 2,650 volt, 408-rev. per min., 12-pole, 90-h.p. induction motor, when run with and without a Kapp vibrator. The natural slip of the motor was 2.75 per cent. at full-load. The curves disclose a slightly undesirable feature which is more or less common to all these phase advancers, namely, that their use increases the slip. The use of a phase advancer, however, greatly increases the instantaneous overload capacity of the induction motor to which it is applied.

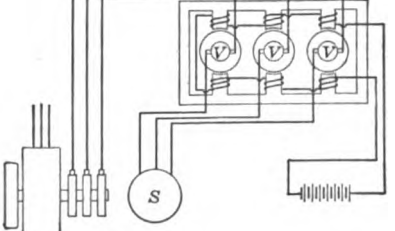

FIG. 183.—Diagrammatic representation of an induction motor and a Kapp vibrator type of phase advancer.

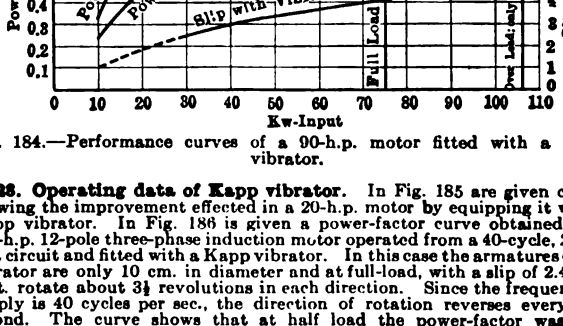

FIG. 184.—Performance curves of a 90-h.p. motor fitted with a Kapp vibrator.

**328. Operating data of Kapp vibrator.** In Fig. 185 are given curves showing the improvement effected in a 20-h.p. motor by equipping it with a Kapp vibrator. In Fig. 186 is given a power-factor curve obtained on a 330-h.p. 12-pole three-phase induction motor operated from a 40-cycle, 2,750-volt circuit and fitted with a Kapp vibrator. In this case the armatures of the vibrator are only 10 cm. in diameter and at full-load, with a slip of 2.45 per cent. rotate about 3½ revolutions in each direction. Since the frequency of supply is 40 cycles per sec., the direction of rotation reverses every *half* second. The curve shows that at half load the power-factor was 0.99 leading; and that at full-load it was 0.96 leading. The corresponding power-

Digitized by Google

factors without the vibrator, were 0.76 lagging and 0.87 lagging respectively. The excitation loss in the fields of the vibrator was only 50 watts.

The Kapp vibrator's chief advantage over revolving types of phase advancers relates to the greater facility with which good commutation may be obtained. Its chief disadvantage relates to its dependence upon a supply of direct current for field excitation.

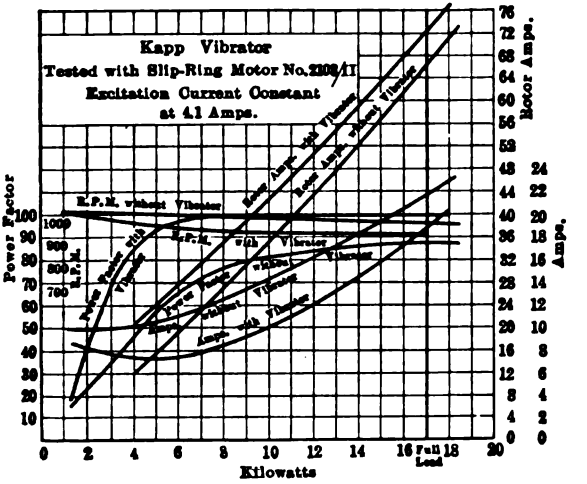

FIG. 185.—Performance curves of a 20-h.p. motor fitted with a Kapp vibrator.

**329. Compensating windings may be used in the Kapp vibrator** and permit of employing stronger armatures, *i.e.*, less flux and more turns. In a preliminary design for a compensated vibrator for a 16-cycle 1,500-h.p. motor, the diameter of the armatures was 13 cm. and their gross core length was 15 cm. In this case the estimated weight for the complete vibrator was 0.5 metric ton. The armatures were calculated to make some 7 to 8 revolutions in each direction and to attain a peripheral speed of about 30 meters per sec. In another design for a vibrator for a 350-h.p., 50-cycle induction motor, the diameter of the vibrator's armatures was 12 cm., and the gross core length was 24 cm. This could be considered as a case in which the conditions were favorable, for the natural slip of the motor was only 1.5 per cent. at rated load and the slip-ring pressure was high, namely, 600 volts. The weight of this vibrator was estimated at 0.55 metric ton, and the calculations indicated that the power-factor would reach 1.00 at one-fourth load, and that there would be a leading current from one-fourth load up to heavy overloads.

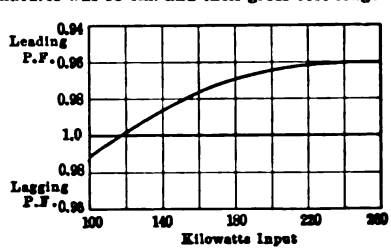

FIG. 186.—Power-factor curve of a 330-h.p. induction motor fitted with a Kapp vibrator.

Digitized by Google

Dr. Kapp puts the cost of the vibrators as ranging from about $1.25 per h.p. in favorable cases, up to $4.00 per h.p. in relatively unfavorable cases, such, for instance, of considerable slip or low-pressure secondary windings or both.

**330. General considerations in the design of phase advancers.** In order to keep down the size and cost of the commutators and the losses at the brushes, it is desirable to wind the secondary of the main motor for fairly high pressure, and it is also desirable that the slip shall be small. It is claimed by Kapp that the smaller the slip, the more favorable is the case for employing a vibrating rather than a rotating phase advancer. The weight and cost per h.p. decrease with decreasing slip and increasing secondary pressure of the main motor. All of these types of phase advancer have the valuable feature of greatly increasing the instantaneous overload capacity of the motors with which they are employed. For a given load the primary current is considerably decreased, and the secondary current increased. This would lead to about the same total copper loss for a given load, were it not for the circumstance that it is usually quite practicable to increase the cross-section of the secondary copper. It is fair to state that the decrease in the losses in the main motor for a given load approximately off-set the losses in the advancer, leaving the efficiency substantially unimpaired at rated load. The efficiency will usually be materially improved at small loads. The power-factor and overload capacity may be both greatly increased.

## MOTOR GENERATORS

**332. General flexibility of combinations.** For transforming alternating electricity from one pressure or phase system to another of the same frequency, stationary transformers usually offer advantages over rotating apparatus. Even for such transformations, however, motor-generator sets permit of adjusting the ratio of transformation at will and over a wide range. This advantage of greater flexibility in the motor generator rarely suffices to justify its use in transformations where it is not desired to alter the frequency. For effecting all other transformations of electricity, motor generators usually represent the most satisfactory means, if questions of cost and efficiency are left out of account.

**333. Motor generators for frequency changing.** Transformations from alternating electricity of one frequency to alternating electricity of another frequency are usually effected by means of synchronous motor-generator sets. Such frequency changer sets are discussed in division headed Par. 346 to 369.

**334. Synchronous converters and motor converters.** The lower cost and higher efficiency of transformations from alternating to direct current by means of synchronous converters (Sec. 9) or motor converters (Sec. 9) justify their use for certain classes of work notwithstanding certain less desirable features.

Digitized by Google

**336. Synchronous-motor drive for motor-generator sets.** The use of a synchronous motor-generator for transforming from alternating to direct current permits of effecting phase control to practically any desired extent; whereas, with a synchronous converter, phase control is only practicable within very narrow limits (Sec. 9). Moreover the direct-current generator of a motor-generator set can be provided with all the desirable attributes of a machine driven by a prime mover. Although the motor-generator set may be employed in a substation many miles away from the generating station, the direct-current generator will have as close speed regulation as the prime movers in the generating station. Its voltage may be controlled through any desired range and it may be provided with a compound winding for giving it practically any characteristics which may be desired. For operating from 60-cycle circuits and for commutator pressures above 1,200 volts, the synchronous converter has a competitor in the synchronous motor-generator set. The motor converter (Sec. 9) is also a rival for such work. For still higher commutator pressures, the synchronous motor-generator set is exclusively suitable for operation from 60-cycle circuits and it is often preferable on 25-cycle circuits.

**336. Induction-motor drive for motor-generator sets.** While it is usually preferable to employ a synchronous motor for a motor-generator set, cases arise where the simplicity of the squirrel-cage induction motor and its lower cost is considered sufficient inducement to employ it notwithstanding its low power-factor. The induction-motor drive is usually confined to relatively small sets and for low voltages at the motor. It is less objectionable at 25 than at 60 cycles, since for a given size and speed the power-factor of induction motors is higher the lower the periodicity.

**337. Starting of motor-generator sets.** It is at present usual to start synchronous motor-generator sets from low-voltage taps of transformers or auto-transformers by means of the torque supplied by squirrel-cage windings fitted in the pole shoes. After the rotor has come up to speed, the stator windings are thrown over to the full-voltage position. The method differs in no essential respect from the "tap" starting of any synchronous motor or rotary converter. Another available method which as yet is but rarely employed in America consists in fitting a small auxiliary induction motor on the shaft with its stator windings either in series with the stator windings of the synchronous motor or else with its stator windings supplied from the secondaries of a series transformer whose primaries are, during starting, in series with the synchronous motor's stator windings. This method is especially appropriate for large sets. As a third method may be mentioned that of starting from the commutator end by temporarily employing the direct-current generator as a motor. Some 25 per cent. of rated full-load current is usually required by this method of starting motor-generator sets. The method is the more worthy of consideration, the higher the frequency of the supply circuit, since tap starting requires more current with the higher frequencies. If the set is started from the commutator end, the compound winding should be temporarily short-circuited by a switch mounted on the frame of the machine or close to it. For this method of starting it becomes necessary to employ synchronizing apparatus. When induction motor-generator sets are employed, one of the motives usually relates to the readiness of starting from the induction-motor end in the same way in which any large squirrel-cage induction motor is usually started up, i.e., by taps from transformers or induction starters.

**338. Motor-generator sets for charging storage batteries.** It might be concluded at first sight that the mercury-arc rectifier would monopolize the function of charging storage batteries when the available supply consists of alternating current. There is, however, a consideration which often weighs decidedly in favor of the motor generator for such work: There is an internal drop of some 20 to 30 volts in the mercury arc rectifier. Let us for explanatory purposes take the drop as 25 volts. Then for supplying electricity at a pressure of 25 volts, the efficiency cannot be greater than $[25/(25+25)] \times 100 = 50$ per cent. But for supplying energy at 250 volts, the efficiency may be of the order of $250/(250+25) = 91$ per cent.

Consequently the higher the required pressure the more appropriate is the mercury-arc rectifier, and the lower the required pressure the more appropriate is the motor-generator. We thus see that for low-voltage storage-battery charging there is an important consideration weighing in favor

Digitized by Google

of the motor generator, although its greater initial cost, the greater cost for attendance, and the general inconvenience inherent to rotating machinery may turn the balance in favor of the mercury-arc rectifier in many instances.

**339. Motor-generator sets for electrolytic work.** The explanations in Par. 338 apply in still greater degree to the provision of direct-current for such electrolytic work as requires a pressure of only a few volts. For such work the required pressure is often of the order of only some 2 to 10 volts. Since the technical problems arising in connection with such sets hinge around the abnormal proportions required for the direct-current generator, and since the alternating-current motor for such sets is entirely normal, this matter is more appropriately discussed in Sec. 8.

**340. Motor-generators for main-line railway substations.** In most main-line railway electrification, direct current will be suplied to the conductor rail or overhead trolley wire at pressures of not less than 1,200 volts and often of from 2,400 volts, to 4,000 volts. Such pressures cannot successfully be provided by synchronous converters or motor converters. Consequently motor-generators will be employed.

**341. Ward Leonard system.** The modern conception associated with the term "Ward Leonard System" is of a system for effecting any desired variations in the speed of a motor for all loads carried by the motor without incurring any rheostatic losses in the main circuit. This is accomplished by interposing a motor-generator set between the variable-speed motor in question and the system from which it is supplied. If the system be one furnishing alternating electricity it will be usual to employ for the motor-generator set a synchronous motor coupled to a direct-current generator. It is arranged that the excitation of the latter may be varied over a wide range by means of a rheostat in its field circuit. The generator's armature and the motor's armature constitute a circuit by themselves which is not interrupted in service. By simple and efficient manipulations of the field rheostats and switch gear in the exciting circuits of the generator, and of the variable-speed motor the latter's speed and direction of rotation are under perfect control at all loads. The system is regenerative; thus, when applied to hoisting, the descending load drives the motor, which, as a generator, reverses the action of the motor-generator set and returns energy to the supply system.

**342. The Ward Leonard system has been applied** to a large variety of work requiring economical operation under widely varying conditions of speed and load. Among these applications is that of operating railway trains: In this instance Ward Leonard has employed single-phase transmission to a motor-generator set on the locomotive. The generator delivers direct current to motors geared to the driven axles. The control is effected exclusively by manipulation of the field excitation. This system of railway electrification was formerly occasionally employed by the Oerlikon Co.

**343. Bibliography of Ward Leonard system.** The system has been described and discussed on several occasions when its inventor presented papers before the American Institute of Electrical Engineers. The following is a list of several papers by H. Ward Leonard relating to his system; these were published, at the various times noted, in the *Trans.* A. I. E. E.

"A New System of Electric Propulsion (June, 1892)," Vol. IX, page 566.

"How Shall We Operate an Electric Railway Extending One Hundred Miles from the Power Station" (Feb., 1894), Vol. XI, page 76.

"Volts vs. Ohms (Speed Regulation of Electric Motors)" (Nov., 1896), Vol. XIII, page 377.

"Multiple Unit, Voltage-speed Control for Trunk Line Service" (Nov., 1902), Vol. XX, page 155.

**344. The Ilgner system.** By providing the motor-generator set with a fly-wheel, Ilgner goes a step farther than Ward Leonard and obtains a system for supplying electricity to a motor which shall carry sharply varying loads at widely varying speeds without imposing any material load variations on the supply system. When operated from a direct-current supply, both members of the motor-generator set are direct-current machines as indicated at *A* and *B* in Fig. 187. The shunt motor *A* is supplied from the direct-current system *G*, and drives the generator *B* and the fly-wheel *C*. It is desired that the motor, *F*, shall be economically operated at any speed in

Digitized by Google

either direction and with widely varying loads. For instance, $F$ may drive reversible rolls in a steel mill or a winder at a coal mine. (Although in the case of such heavy work, the supply would consist in polyphase electricity, it is simpler first to describe the arrangement employed with a supply of continuous electricity.) It will be observed that there are no switches or rheostats in the circuit of the armatures of the generator $B$, and the variable-speed motor $F$. The excitation for the latter may be supplied from $G$, as indicated in the diagram. The control of the speed of $F$ is effected by control of the field excitation of the generator $B$ by means of the rheostat $D$. The direction of $F$ is controlled by the switch $E$. Assuming the case of winding a load up out of a shaft, let us take the moment when the load is at rest at the bottom. Switch $E$ will be open at this moment and $F$ will be at rest. To wind up the load the switch $E$ is closed in the right direction and the field of $B$ is rapidly strengthened by cutting out the rheostat $D$, point by point. This accelerates the motor $F$ to its full speed.

The load thus imposed on the fly-wheel motor-generator set is largely provided from the energy stored up in the fly-wheel $C$. By the time the wind is completed, the motor generator's speed has decreased a few per cent. During the descent, the motor $A$ is still loaded, since it is accelerating the fly-wheel to its full speed and storing energy in it. The descending load may contribute to the process by regeneration.

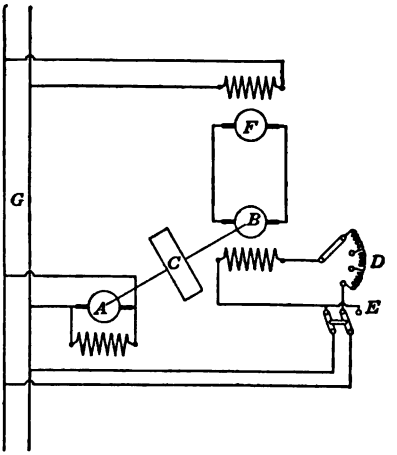

FIG. 187.—Ilgner system.

**345. Field of application of the Ilgner system.** The Ilgner system has been extensively used and instances are on record of reversing rolling mills in which load variations of enormous amount occurring many times per min. are so effectively equalized as to occasion practically constant load on the supply system. See Sec. 15. However, for heavy work of this character, the supply consists of polyphase energy, and an induction motor replaces the direct-current motor $A$ of the motor-generator set. But the generator $B$ and the variable-speed motor $F$ remain direct-current motors, and the operation is quite as explained above. It is, however, necessary to provide an exciter for the field winding of $F$. Furthermore, certain details are introduced relating to the automatic insertion of resistance in the secondary windings of the induction motor of the motor generator, in order to control the rate and extent of deliverance of the kinetic energy of the fly-wheel.

## FREQUENCY CHANGERS

**346. Field of application of the frequency changer.** With the rapidly extending employment of electricity as a means of transmitting energy to a distance, it has come about that most civilized regions of the world are now provided with enormous networks of transmission conductors. Various networks in neighboring localities are often the outgrowth of small undertakings which were originally in competition with one another, and they differ as regards pressure, phase system, and frequency. At the present stage of development it is becoming important to interconnect these systems. The difference in pressure and phase system are readily reconciled by means of stationary transformers, Sec. 6. But the different *frequencies* can only be dealt with commercially in the linking-up process by means of rotating ma-

Digitized by Google

chinery termed "frequency changers." Such machines are also required when, for a portion of the load on a system, a different frequency is appropriate from that required for the bulk of the load. Thus single-phase railways are less unsatisfactory the lower the frequency employed. Consequently when a large 60-cycle power-supply undertaking contracts to supply a single-phase railway, frequency changers must be employed to provide electricity of a frequency of 25 or preferably 15 cycles per sec. In Europe a periodicity of 16.66 cycles per sec. has been standardized for single-phase railways, and 50 cycles for general power and lighting purposes. Without devoting more space to a specific discussion of the occasions for frequency changers, we may briefly subdivide these occasions into two groups relating, respectively: first, to the case of the exclusive supply of electricity through a subsidiary system with no other source of power, at a frequency differing from that of the main system, and, secondly, to the linking up of two systems of different frequencies, each system also having its own independent generating plant. While the first case is relatively simple, a number of important considerations involving attention to complex details arise in connection with the second case.

**347. Frequency changers for the exclusive supply of subsidiary networks.** Let us now deal with the first case and base our explanations on the example of a circuit for which 25-cycle energy is required, the frequency of the main system being 60-cycles. The simplest plan, and the one almost always adopted, consists in employing a synchronous motor-generator set, the motor of which is designed to run at 60-cycles while the generator is designed with such a number of poles that, when driven by the motor, its frequency will be 25 cycles per sec. The smallest number of poles for these two combinations are 24 for the motor and 10 for the generator, since $24/2 = 12$, and $10/2 = 5$ are the smallest whole numbers bearing to one another the ratio of 60 to 25. A 24-pole motor on a 60-cycle circuit runs at $(60 \times 60)/12 = 300$ rev. per min. It is usually desirable to select the smallest practicable number of poles, since this corresponds to the highest speed and consequently to the smallest and cheapest motor-generator set. The synchronous motor of such a set may be designed with an appropriate squirrel-cage (amortisseur) pole-face winding to enable it to run up to speed as an induction motor. In this case it will be started from low-pressure taps of a transformer or induction starter as described in Par. **337**. As an alternative, it may be started by means of an induction motor in series as also mentioned in Par. **337**, and will be self-synchronizing. In other instances it may be preferred to employ an auxiliary direct-current motor to bring the set up to speed. After the set is in synchronism, the 25-cycle load may be supplied from the generator. Synchronous frequency changers have the good feature that by overexciting the synchronous motors, they can be made to also act as synchronous condensers to improve the power-factor of the system as described in Par. **319** and **320**.

**348. Induction motor versus synchronous motor as primary member of a frequency changer set.** Except for this last feature (Par. **347**), it may occasionally be preferable in such a case to employ a motor of the non-synchronous type and with a squirrel-cage rotor. But by such a plan a lagging load will be imposed upon the main system and this will usually be so objectionable that it will more than offset the advantage of simplicity possessed by the squirrel-cage induction motor. Furthermore, it will not permit us to dispense with a supply of direct-current for excitation, since this will be required in any case for providing the excitation for the generator member of the motor-generator set. In exceptional cases it might be a good plan to let the motor be of the induction type and arrange to operate it at unity or leading power-factor by the employment of a phase advancer of one of the types discussed in Par. **331** to **331**. The Brooklyn Edison Co. has 1,000-kw. and 500-kw. induction-motor-driven frequency-changer sets (which have been supplied by different manufacturers) operating in parallel.

**349. The parallel operation of two or more frequency changers.** If two or more frequency changers of the synchronous motor-generator type mentioned in Par. **333** and **347** are required to operate in parallel in supplying a load, certain complications arise due to the necessity for synchronizing the frequency changers at both ends, and due to the requirement that the internal reactance and shifting of magnetic axes in the machines (with loads varying as regards amount or phase) shall not be such as to cause

Digitized by Google

inappropriate division of the load among the different machines in parallel. These matters have been carefully considered by J. B. Taylor in a paper entitled "Some Features Affecting the Parallel Operation of Synchronous Motor-generator Sets," published in Proceedings of the American Institute Electrical Engineers, Vol. XXV (1906), p. 113 and by N. E. Funk in a paper entitled "Operation of Frequency Changers" at p. 1579 of the July, 1913, issue of the Proceedings American Institute Electrical Engineers. The relations involved are too complicated to be satisfactorily abstracted. Let us, however, consider the matter briefly by reference to the case of supplying 40 cycles from a 60-cycle system through two sets, each consisting of a 6-pole 1,200-rev. per min. synchronous motor, direct-connected to a 4-pole synchronous generator. Let us assume that the relative angular positions of the generator and motor fields are as shown in Fig. 188, see *I* and *II*. Set *I* is in service and it is desired to place set *II* in parallel with it. The large letters *N* and *S* relate to the North and South poles of the 6-pole motors and the small letters *n* and *s* to the poles of the 4-pole generators. It is not only necessary that the North poles of *II* shall occupy the same angular positions as the North poles of *I*, but it is furthermore necessary that a particular

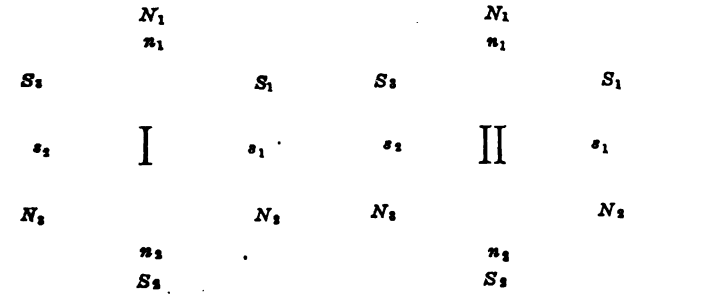

FIG. 188.—Correct angular relation of two frequency-changer sets for parallel operation.

North pole $N_1$ of *II* shall occupy the same angular position as a particular North pole $N_1$ of *I*. It is not permissible that $N_2$ or $N_3$ of *II* shall be synchronized with $N_1$ of *I*, since then a North pole of the generator of set *II* could not be brought into the same angular position as a North pole of the generator of set *I*.

**350. Synchronising unloaded frequency changers.** Thus, when synchronising at random, there is only one chance in three that the desired relative positions will be obtained. Consequently after synchronizing the two motors, the fields of one of them will usually have to be reversed either once or twice, before the correct relative positions of the two generator fields is obtained.

**351. Synchronising loaded frequency changers.** If, when it is desired to add set *II* to the system, set *I* is, as will usually be the case, already loaded, then the *magnetic* axes in set *I* will be displaced from the *geometric* axes and this displacement will not be exclusively a function of the amount of the load but will also be greatly dependent upon whether it is in phase or whether and to what extent it is lagging or leading. The matter is increased in complexity when frequency-changer sets of different designs and capacities are to be operated in parallel. When care has not been exercised in the original designs, it has often proved impossible to arrange to divide the load in proper proportions between the different sets. One set may take too great a share at light loads and too small a share at heavy loads, or one set may take too great or too small a share at all loads. All these troubles may be avoided by the application of known principles, but there have in the past been many instances in which factors requiring careful attention have been overlooked. Funk in the paper to which

Digitized by Google

reference has already been made, describes interesting arrangements for synchronising frequency-changer sets when operating in parallel.

**352. Refinements of construction necessary to permit of parallel operation.** From the above discussion it will be evident that in order to obtain an appropriate division of the load between two frequency changer sets operated in parallel, great exactness in construction and adjustments is necessary. It is desirable to be able to effect a final mechanical adjustment of the stators with relation to one another. This is often arranged by providing a cradle construction. The stator of one machine is bolted to a cradle fastened to the base. By "slacking off" the bolts, a small angular adjustment of the stator may be effected, and the bolts afterward tightened.

**353. Efficiency of a motor-generator frequency changer.** By using a motor-generator set as a frequency changer, each of the two machines has to be proportioned for the entire load to be delivered to the changed-frequency circuit, and the set is consequently large and expensive. Furthermore, if each machine has an efficiency of, say, 95 per cent., the combined efficiency is only 91 per cent. since $0.95 \times 0.95 = 0.91$.

**354. Induction-type frequency changer.** We shall now consider means by which better results, in these respects, may sometimes be obtained. These means rest fundamentally upon the circumstance that, in an ordinary polyphase induction motor, the frequency of the current in the rotor winding depends upon the speed of the rotor. Let us consider a 60-cycle three-phase induction motor with a three-phase rotor and three slip-rings. If the stator windings are connected to a 60-cycle circuit, then, if the rotor is restrained from moving, the frequency in the rotor windings will also be 60-cycles per sec. If, on the contrary, the rotor's speed is the same as that of the revolving magnetic field in the stator, and in the same direction, then the frequency in the rotor winding will be zero. Thus if the 60-cycle induction motor has four poles, the magnetic field will travel around the stator at a speed of: $(60 \times 60) \div (4/2) = 1{,}800$ rev. per min.

If the rotor's speed is also 1,800-rev. per min. and in the same direction, then the frequency in the rotor windings will be zero. If, however, the rotor's speed is only 1,200 rev. per min. the frequency will be $[(1{,}800 - 1{,}200)/1{,}800] \times 60 = 20$ cycles per sec. If the rotor's speed is only 300 rev. per min., the frequency will be $[(1{,}800 - 300)/1{,}800] \times 60 = 50$ cycles per sec. If the rotor is restrained from running, the frequency will be $[(1{,}800 - 0)/1{,}800] \times 60 = 60$ cycles per sec. If the rotor is driven at a speed of 300 rev. per min. in a direction opposite to that of the magnetic field in the stator, the frequency will be $[(1{,}800 + 300)/1{,}800] \times 60 = 70$ cycles per sec.

In our case we wish a frequency of 25 cycles per sec. Consequently, if we denote by $R$ the speed at which we shall drive the rotor we may have either $[(R - 1{,}800)/1{,}800] \times 60 = 25$ or $[(1{,}800 - R)/1{,}800] \times 60 = 25$ and $R = 2{,}550$ or $R = 1{,}050$.

**355. Direct-current motor drive for induction-type frequency changer.** Let us select the former case and drive the rotor at a speed of 2,550 rev. per min., by another motor. We can only do this if we have a source of supply of continuous electricity and employ a 2,550 rev. per min., continuous-electricity motor. We could not employ a 60-cycle induction motor to drive the rotor since this would run at only 1,800 rev. per min., if wound with 4 poles and at 3,600 rev. per min., if wound with 2 poles, and we require it to run at 2,550 rev. per min.

**356. Alternating-current motor drive for induction-type frequency changers.** If there is no source of continuous electricity supply, thus limiting us to the use of a 60-cycle motor to drive the rotor of the frequency changer, then we shall have to abandon the plan of employing a 4-pole frequency changer and we shall be obliged to employ one with more poles which, consequently, will be heavier and more expensive. We can determine upon a suitable combination by consulting the table in Par. **357**.

**357. Selection of proper speed and number of poles in induction-type frequency changers.** In the table given in Par. **358**, the smallest number of poles which, in column *IV*, corresponds to the synchronous speed of a 60-cycle motor, is 14, corresponding to a rotor speed of 300-rev. per min. Our frequency changing outfit thus consists of a 14-pole induction motor with its rotor driven by a 300-rev. per min., 60-cycle synchronous motor which will, consequently, have $2 \times [(60 \times 60)/300] = 24$ poles. But, for so

Digitized by Google

slow a speed, the outfit will be heavy and expensive. Examining column V of the table we see that for an 8-pole frequency changer in which the rotor is driven at a speed greater than that of the stator field, the required speed is 1,275 rev. per min. Since a 6-pole, 60-cycle synchronous motor runs at a speed of only 1,200 rev. per min., the frequency will be only $(1,200/1,275) \times 25 = 23.5$ cycles per sec.

It has been assumed that the frequency changer is required for supplying an independent circuit which has no other source of supply. In such a case, a periodicity of 23.5 cycles would usually be nearly as appropriate as 25 cycles. If, on the other hand, we were to elect to employ a 6-pole frequency changer, the rotor speed required for 25 cycles would, as seen from column V, be 1,700 rev. per min., and if we arranged to drive it by a 4-pole synchronous motor, the speed would be 1,800 rev. per min., giving $(1,800/1,700) \times 25 = 26.5$ cycles per sec. If, in the latter case, we were to employ a squirrel-cage induction motor to drive the rotor, instead of employing a synchronous motor, and if we were to design the induction motor for a full-load slip of 5.5 per cent., then the periodicity would vary from 26.5 cycles, at no-load, to $26.5 \times 0.945 = 25.0$ cycles, at full-load. Enough has been said to indicate that the circumstances of each proposed installation will largely govern the suitable design.

**358. Table of relative speeds for induction-type frequency changers**

| Number of poles of stator of frequency changer | Speed of magnetic field in stator when excited from 60-cycle circuit | Required relative speed of stator field and rotor in order to provide 25 cycles in rotor | Speed at which rotor must be driven | |
|---|---|---|---|---|
| | | | Rev. per min. | |
| | | | If below speed of stator field | If above speed of stator field |
| *I* | *II* | *III* | *IV* | *V* |
| 2 | 3,600 | 1,500 | 2,100 | 5,100 |
| 4 | 1,800 | 750 | 1,050 | 2,550 |
| 6 | 1,200 | 500 | 700 | 1,700 |
| 8 | 900 | 375 | 525 | 1,275 |
| 10 | 720 | 300 | 420 | 1,020 |
| 12 | 600 | 250 | 350 | 850 |
| 14 | 514 | 214 | 300 | 728 |
| 16 | 450 | 187.5 | 262.5 | 637.5 |
| 18 | 400 | 166.7 | 233.3 | 566.7 |
| 20 | 360 | 150.0 | 210.0 | 510.0 |
| 22 | 327 | 136.5 | 190.5 | 463.5 |
| 24 | 300 | 125.0 | 175.0 | 425.0 |
| 26 | 277 | 115.3 | 161.7 | 392.3 |
| 28 | 257 | 107.0 | 150.0 | 364 |

**359. A disadvantage of induction-type frequency changers** relates to the need for delivering energy to the system from the slip-rings of the rotor. This limits the voltage which can be supplied to the low value for which it is expedient to wind a rotating element, and may entail the necessity for a step-up compensator or transformer. The outfit also requires the inclusion of some form of potential regulator to provide the precise voltage required at all loads.

**360. Power required to drive the rotor of an induction-type frequency changer.** In induction types of frequency changer, irrespective of whether the rotor is driven by a direct-current motor, a synchronous motor, or an induction motor, the output required of the motor driving the rotor will (if the rotor is driven in the same direction as the stator field) be equal to the output from the frequency changer plus the copper losses in the latter's rotor circuits. If, on the contrary, the rotor is driven in opposition to the stator field, the output required from the driving motor is only proportional to that part of the frequency which it adds to the frequency impressed by the main circuit. For example, if 60-cycles is required from a 50-cycle circuit,

Digitized by Google

we may employ a 4-pole frequency changer and drive its rotor at 300 rev. per min. in opposition to the 1,500 rev. per min. of the stator field. If the output delivered from the frequency changer is 1,000 kw., then $(300/1{,}800) \times 1{,}000 = 167$ kw. is provided by the driving motor and $(1{,}500/1{,}800) \times 1{,}000 = 833$ kw. is provided by the frequency changer itself in its transformer capacity, and at high efficiency.

Obviously the less the required alteration in frequency, the greater is the appropriateness of the induction-type of frequency changer as compared with the motor-generator type.

**361. Relative merits of various kinds of motors for driving the rotor of an induction-type frequency changer.** Whether or no it may be practicable to employ an induction motor to drive the rotor, depends to a considerable extent upon the importance or otherwise of supplying absolutely constant frequency at all loads. When it is permissible that the frequency may decrease 1 or 2 per cent. or more from no-load to full-load, an induction motor may provide the most satisfactory solution, since it eliminates the necessity for having a supply of continuous electricity for excitation.

In some instances instead of employing a squirrel-cage induction motor and then having a slip necessarily proportional to the load, it becomes appropriate to drive the frequency changer's rotor by a slip-ring induction motor and regulate its slip, and consequently the frequency supplied, by regulating the resistance in its rotor circuits. This becomes the more expedient, the smaller the proportion of the total energy which is supplied by the driving motor. For instance, in the example in Par. 360, only $(300/1{,}800) \times 100 = 16.7$ per cent. of the total output, is provided by the driving motor, and a considerable rheostatib loss in its rotor circuits would not seriously affect the efficiency of the complete outfit. It should again be emphasized that induction-type frequency changers are not used in commercial practice. Synchronous motor-generator sets are practically always employed.

**362. Frequency changers for connecting two systems, each of which has its own generating machinery of fixed frequency.** We now come to the problem encountered when frequency changers are employed between two systems each of which has a definite frequency imposed upon it by its own generating plant. Synchronous motor-generator sets have nearly always been employed for this class of work. Thus, in order to link up two systems with frequencies of 60 and 25 cycles per sec., respectively, two synchronous machines of 24 and 10 poles respectively are coupled together. It is necessary for the frequencies of the two systems to be exactly identical in order to successfully operate such plant. Furthermore, there are the various complicated relations necessarily observed in synchronising such apparatus, as already discussed in Par. 349.

Indeed, there is the further consideration that when **sets for parallel operation** are so proportioned and adjusted that they share the load in appropriate proportions when delivering power from, let us say, a 25-cycle system to a 60-cycle system, the division of the load will be altered when it is desired to reverse the sets and deliver power from the 60-cycle set to the 25-cycle system. Notwithstanding the niceties imposed by the relative-frequency conditions, synchronous motor-generator sets constitute the usual means employed.

When synchronous sets are employed to link two large systems, the slightest alteration in the relative frequencies of the two systems occasions enormous fluctuations in the load carried by the frequency changers. This difficulty is less the greater the size of the frequency changers as compared with the size of the systems connected. Unless the frequency changers are of large size as compared with the size of the systems which they connect, they will be pulled out of step if there is any slight change in the ratio of the frequencies of the two systems. Consequently, when the frequency changers cannot be of relatively great size, it would be preferable to employ sets in which an induction machine constitutes the motor member.

**363. Induction-motor drive for non-reversible frequency changers.** Where the object is to deliver energy always in the same direction, the employment of an induction machine with a slip-ring rotor as motor element, and the control of its precise speed by the adjustment of a rheostat in its rotor circuits provides freedom from the necessity for maintaining at exactly the same value the ratio of the frequencies of the inter-connected systems.

Digitized by Google

Indeed any slight change in the ratio of the frequencies is automatically accompanied by an appropriate alteration in the slip of the induction motor and this alteration is of such a nature as to reduce the accompanying load variation to a moderate amount.

**364. The use of an induction machine in a reversible frequency changer.** It has even been suggested that by the adoption of suitable pole numbers and by providing sufficient range of slip-control by the resistances in the rotor circuits, such a set could be employed reversibly. In such a case the induction machine would function as a generator to an extent which may be controlled by adjustment of the resistances in the rotor circuits.

**365. Frequency changing by two induction machines.** Both machines could be of the induction type, the one operating as a motor and the other as a generator. This arrangement, if required to be reversible, would, however, only be possible for connecting two systems each of which is provided with synchronous apparatus, since the generator member would be dependent upon such apparatus for its excitation. Each machine would have a slip-ring rotor and the amount and direction of the load would be controlled by adjustment of the amount of resistance in the rotor circuits.

**366. Position of shaft in frequency changers (horizontal or vertical).** While frequency changers are usually built with horizontal shafts, the vertical type offers the advantage in large sets that an economy in floor space is effected. The construction may also permit of reduced friction losses.

**367. Number of bearings in frequency changers.** Where floor space is restricted, sets with only two bearings are occasionally employed. Three-bearing designs are, however, to be preferred. They afford better opportunity for circulation of air through the machine, since the shaft may be smaller. Such designs also provide for more ready access to all parts.

**368. Pairs of rotary converters as frequency changers.** It has been proposed to accomplish frequency transformation by the employment of two rotary converters arranged with their alternating-current ends connected to the circuits of the two frequencies and with the commutators in parallel. This plan of transforming from alternating electricity of one frequency into continuous electricity and then into alternating electricity of another frequency avoids the difficulties of speed inflexibility of synchronous motor generators while retaining their desirable feature as regards power-factor control.

**369. Literature relating to frequency changers** is rather meagre. The most important contributions are: J. B. Taylor's paper entitled, "Some Features Affecting the Parallel Operation of Synchronous Motor-generator Sets," Proc. A. I. E. E., Vol. XXV (1906), p. 113, and N. E. Funk's paper entitled, "Operation of Frequency Changers," Proc. A. I. E. E., July, 1913, p. 1579.

In the *Electrician*, Sept. 27, 1912, page 1021, is an article by C. Turnbull, entitled, "Frequency Changers." In the *General Electric Review*, August, 1913, page 609, are some notes on "Frequency-changer Sets." In the *General Electric Review*, Dec., 1913, page 941, is an excellent article by Gordon Harris and L. B. Bonnett entitled, "Frequency Changers," which covers the main considerations thoroughly.

# SECTION 8

## DIRECT-CURRENT GENERATORS AND MOTORS

### GENERAL PRINCIPLES

**1. Lines of magnetic flux.** A magnetic field may be represented by continuous lines, called lines of flux, whose direction at any point in the field is that of the force acting on a north pole placed at the given point; they therefore emerge from a north pole and enter a south pole (Sec. 2).

**2. Electromagnetic induction.** When the total magnetic flux threading a coil undergoes a change, an electromotive force (e.m.f.) is generated or induced in the coil. This e.m.f. is proportional to the time rate of change of flux. One volt is generated in a coil of one turn when the rate of change of flux threading the coil is $10^8$ lines per sec.

**3. Magnitude of induced e.m.f.** In Fig. 1, $N$ and $S$ are respectively the north and south poles of a magnet and $\phi$ represents the direction of the magnetic flux passing from the north to the south pole. When coil $A$ is moved from position 1 where the flux threading the coil is $\phi$, to position 2 where the flux threading the coil is zero, in $t$ sec., the average e.m.f. generated in the coil is $E = (\phi/t)\ 10^{-8}$ volts.

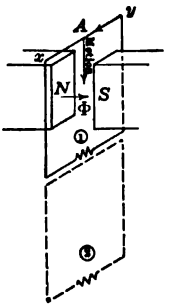

FIG. 1.—Direction of generated e.m.f.

**4. The direction of the generated e.m.f.** may be found by **Fleming's right-hand rule**, which states that if the thumb, forefinger, and middle finger of the right hand be placed at right angles to one another so as to represent three coordinates in space, with the thumb pointed in the direction of motion of the conductor relative to the field, and the forefinger in the direction of the lines of flux, then the middle finger will point in the direction of the induced e.m.f. (Sec. 2). The direction of the e.m.f., found by Fleming's rule, is shown by the arrow in Fig. 1, and it may be seen (Sec. 2), that the magnetic effect of the current produced tends to prevent the flux threading the coil from decreasing or, as stated by Lens's law (Sec. 2), the generated e.m.f. always tends to send an electric current in such a direction as to oppose the change of flux which produces it.

**5. Force on a conductor in a magnetic field.** A conductor $L$ cm. long, carrying a current of $I$ amp. perpendicular to a magnetic field of $\mathfrak{B}$ lines per sq. cm., is acted on by a force of $\mathfrak{B}LI/10$ dynes in a direction found by **Fleming's left-hand rule**, which states that if the thumb, the forefinger and the middle finger of the left hand be placed at right angles to one another so as to represent three coordinates in space, with the thumb pointed in the direction of the force on the conductor and the forefinger in the direction of the lines of flux, then the middle finger will point in the direction of the current.

**6. Identity of generator and motor structure.** Diagram $A$, Fig. 2, shows a generator under load; the direction of rotation is determined by the prime mover, while the direction of the current in the conductors may be found by the right-hand rule (Par. 4). A force is exerted on the conductors, inasmuch as they are carrying current in a magnetic field; the direction of this force is found by the left-hand rule (Par. 5) and is opposed to

Digitized by Google

the direction of motion of the armature. The driving force must be large enough to overcome this retarding force and also to overcome the friction of the machine.

Diagram *B* shows the same machine acting as a motor. In this case the direction of the current is determined by the polarity of the connected line, while the direction of motion is that of the force on the conductors and may be found by the left-hand rule (Par. 5). Since the motor armature revolves in a magnetic field, an e.m.f. will be generated in the conductors. The direction of this e.m.f., found by the right-hand rule, is opposed to the direction of the current. The applied e.m.f. must be large enough to overcome this **counter e.m.f.** and also to send the current through the resistance of the armature.

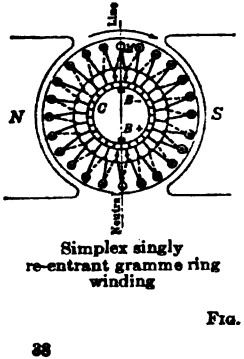
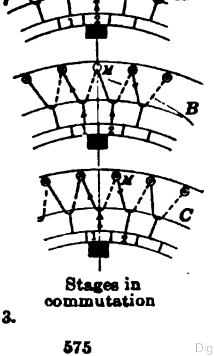
FIG. 2.—Direction of current in generator and motor.

**7. Armature circuits.** Armature conductors must be connected together in such a way that a desired resultant e.m.f. may be maintained between two terminals connected to the external circuit. Fig. 3 represents a type of connection known as the **Gramme ring winding** in which all the conductors are connected in series. Each conductor is marked with a dot (within the circle) when the direction of the e.m.f. is *toward* the reader and by a cross (within the circle) when the direction is *from* the reader. Between the lowermost and the uppermost conductors, represented as crossing the **neutral axis**, there are two conductive paths through the winding, but inasmuch as the e.m.fs. generated in these paths are equal and opposite, no current can flow until the brushes *B* are placed on the commutator *C*. By the latter means the equal and opposite e.m.fs. of the two halves of the armature winding are connected in parallel with respect to the external circuit. The commutator consists of a number of copper blocks connected to various points of the winding, but insulated from one another.

**8. Commutator and brushes.** As the armature in Fig. 3 revolves, the coil *M* passes from one side of the neutral line to the other, and the direction of the current in this coil is shown at three successive instants in diagrams *A*, *B* and *C*. As the armature moves from *A* to *C* and the brush changes contact from segment 2 to segment 1, the current in coil *M* is automatically reversed. For a short period the brush is in contact with both segments, and during this interval the coil is short-circuited; it should therefore be in such a position that no



Simplex singly re-entrant gramme ring winding



Stages in commutation

FIG. 3.

Digitized by Google

e.m.f. is being generated in it, that is, it should be midway between the poles or in the neutral position.

**9. Field excitation.** The m.m.f. necessary to establish the flux in the magnetic circuit is obtained by means of field coils which are wound upon the poles of the machine. The exciting current for the field coils may be supplied in various ways. When a generator supplies its own exciting current it is said to be **self-excited**; when the exciting current is supplied from some external source, such as an exciter, the machine is said to be **separately excited**. The different connections used are shown diagrammatically in Fig. 4.

Diagram *A* shows a separately excited machine. Diagram *B* shows a **shunt machine**, in which the field coils form a shunt across the armature terminals and have many turns of small wire carrying a current which is proportional to the terminal voltage of the machine. This field current seldom exceeds 5 per cent. of the armature current under full-load conditions. Diagram *C* shows a **series machine**, in which the field coils are in series with the

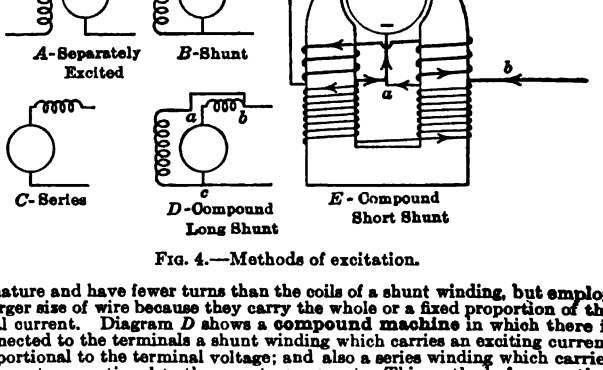


FIG. 4.—Methods of excitation.

armature and have fewer turns than the coils of a shunt winding, but employ a larger size of wire because they carry the whole or a fixed proportion of the total current. Diagram *D* shows a **compound machine** in which there is connected to the terminals a shunt winding which carries an exciting current proportional to the terminal voltage; and also a series winding which carries a current proportional to the armature current. This method of connection is known as the "**long shunt.**" Diagram *E* shows a compound machine connected in another manner. The connection in this case is known as the "**short shunt**"; that is, the shunt coil is connected to the terminals of the armature. Small machines using permanent magnets for field poles are called **magnetos.**

## CLASSIFICATION OF TYPES

**10. Classification according to the number of poles,** as follows:

(a) **Bipolar machines** (Fig. 4) have only two poles.

(b) **Multipolar machines** (Fig. 46) have more than two poles; the number of poles is always a multiple of two.

(c) **Homopolar machines** (Fig. 89) have two poles, but the conductors always cut lines of unidirectional flux. The resulting e.m.f. is continuous in one direction and therefore no commutator is required.

**11. Classification according to the method of drive,** as follows:

(a) **Belted-type motors and generators** are self-contained. This type of machine includes bearings, shaft extended for a pulley and a sliding base with belt-tightening device. An outboard bearing is usually provided with machines of larger capacity than 200 kw. at 600 rev. per min.

(b) **The engine-type generator** has its armature mounted on a continuation of the crank shaft of the engine, and **slow-speed units** are generally

Digitized by Google

supplied without base, bearings, or shaft, these being furnished by the engine builder.

(c) **The direct-connected turbo-generator** has its armature shaft coupled directly to that of a steam turbine. In this type the construction of the generator is special on account of the high speed.

(d) **The geared turbo-generator** has its armature shaft connected to the shaft of a steam turbine through a reduction gear, so that a generator of moderate speed and simple construction may be used.

(e) **The water-wheel type generator** has its armature shaft coupled directly to that of a water wheel. Such a generator may be of either the horizontal or the vertical type and is generally supplied complete with base, bearings, shaft and coupling.

(f) **The back-geared type motor** embraces a speed-reduction gear as an element of the machine. The slow-speed shaft is supported in bearings attached to the frame.

**12. Classification according to special features of construction,** as follows:

(a) **Interpole machines** (Fig. 24) have small auxiliary poles which carry series windings and improve commutation.

(b) **Compensated machines** (Fig. 27) have series windings on the pole faces to neutralise armature reaction. Such machines may also have interpoles.

(c) **Miscellaneous.** Under this class may be included **mill motors,** used in rolling mills; **flame-proof motors** for mine service; **variable-speed generators,** for train lighting; etc. (Par. **183** to **215**).

## ARMATURE WINDINGS

**13. The Gramme ring winding** is almost obsolete; examples of it are shown in Figs. 3, 5, and 6 merely to present clearly the meaning of the terms used in describing the various types of winding.

**14. A re-entrant winding** closes or re-enters on itself. **A singly re-entrant winding** closes on itself only after including all of the conductors; see Figs. 3 and 6. **A doubly re-entrant winding** closes on itself after including half of the conductors; see Fig. 5.

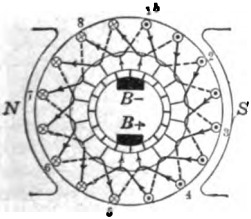

FIG. 5.—Doubly re-entrant duplex winding.

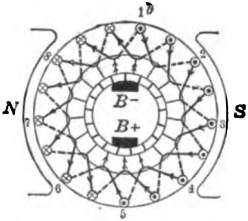

FIG. 6.—Singly re-entrant duplex winding.

**15. A simplex winding** has only two paths through the armature from each brush; see Fig. 3. **A duplex winding** has twice as many, or four paths, through the armature from each brush. In this winding each brush should cover at least two commutator segments; see Figs. 5 and 6. Although it is possible to use **multiplex** and **multiply re-entrant** windings, they are seldom found in modern machines. Even duplex windings are rarely used except for machines of very large current capacity.

**16. The drum winding** has coils shaped as shown in Fig. 7. At any instant, two sides of each coil are under adjacent poles. Since the number of conductors in each coil must be a multiple of two, the total number of conductors must be even. A winding made with coils of this shape must lie in two layers and is called a **double-layer winding.**

**17. Representation of drum windings.** Fig. 8 shows a double-layer

Digitized by Google

drum winding corresponding to the Gramme ring winding in Fig. 8. It has the same number of conductors and the same number of paths through the armature, but only half the number of commutator segments. Conductors in the upper layer are represented by full lines and those in the bottom layer by dotted lines. The radial lines represent face conductors; the connecting lines on the inside represent the connections at the commutator end, and those on the outside represent the connections at the opposite end. For convenience the brushes are shown inside the commutator.

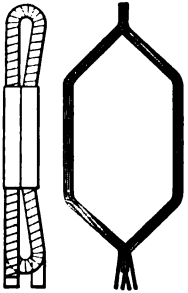

FIG. 7.—Coil group for double layer winding with two turns per coil and eight conductors per slot.

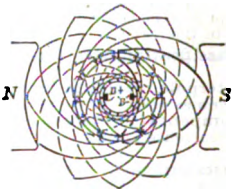

FIG. 8.—Simplex singly re-entrant drum winding.

**18. Multiple winding.** Fig. 9 shows a six-pole drum winding with six paths in parallel between the positive and the negative terminals. The three positive brushes are connected together outside of the machine by a copper ring $T_+$, and the three negative brushes are connected by a similar ring $T_-$. This winding is of the multiple type, that is, the number of armature circuits between terminals is a multiple of the number of poles.

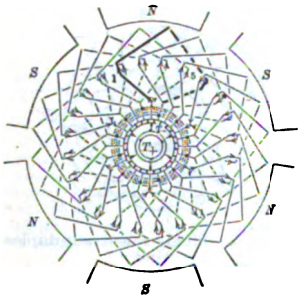

FIG. 9.

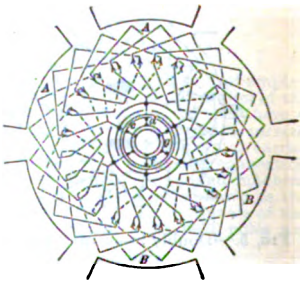

FIG. 10.

FIGS. 9 AND 10.—Simplex, singly re-entrant, full-pitch multiple winding with equalizers.

**19. Equalizers.** Fig. 10 shows a multiple-wound armature which is not central with the poles. The flux density in the air gaps $A$ is greater than that in the air gaps $B$, and the voltage generated in a circuit under poles $A$ is greater than that in a circuit under poles $B$, so that the generated voltage between $c$ and $d$ is greater than that between $f$ and $g$; hence a **circulating current** will flow through the winding and brushes, causing sparking, additional loss and additional heating. This circulating current may be minimized by careful centering during erection, while the sparking may be pre-

Digitized by Google

vented by providing a low-resistance path of copper between $c$ and $f$, and also one between $d$ and $g$ (shown outside of the brush circle), so that the circulating current will flow through this path rather than through the brushes. These equalizer connections, as the low-resistance paths are called, do not eliminate the circulating current, but merely prevent it from passing through the brushes.

An armature is completely equalized by connecting together all commutator segments which should be at the same potential. However, it is usual to provide about 30 per cent. of the maximum number of equalizer connections and make their cross-section equal to half the cross-section of the armature conductor. The equalizer connections shown in Fig. 9 are located behind the commutator. In this position it is difficult to reach them for repair; consequently it is usual to connect the equalizers to the windings at the rear end of the machine.

**20. The number of slots and the number of commutator segments,** in a multiple-wound armature supplied with equalizers, should, for a simplex winding, be a multiple of $p/2$, the number of pairs of poles.

**21. Pitch of winding.** The winding shown in Fig. 9 is a **full-pitch winding** or one in which the width of the coil exactly equals the pole pitch. Fig. 11 shows part of a **short-pitch winding** or one in which the width of the coil is less than the pole pitch.

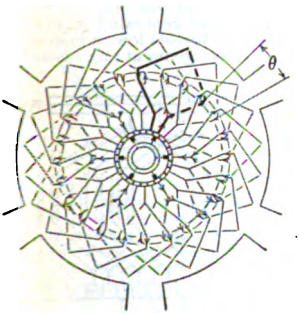

FIG. 11.—Simplex singly re-entrant short-pitch multiple winding.

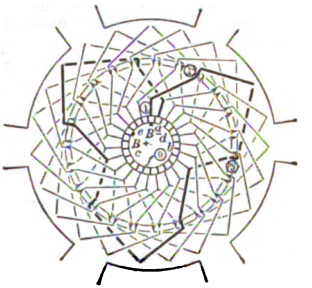

FIG. 12.—Two-circuit progressive winding.

**22. Two-circuit or series winding.** Fig. 12 shows a six-pole drum winding with only two paths between the positive and the negative terminals. Only two sets of brushes are required and each brush short-circuits $p/2$ coils in series. Since the points $a$, $b$, and $c$ are all at the same potential, and also the points $d$, $e$, and $f$, it is possible to place brushes on the commutator at each of these points, so that the current may be collected from three sets of brushes instead of from one, and a shorter commutator may be used. A machine with a two-circuit winding has generally as many brush sets as there are poles.

**23. The number of commutator segments** in a two-circuit winding must not be a multiple of the number of pairs of poles, for otherwise the winding, after it had passed once around the armature, would close upon itself. To be singly re-entrant, the winding must progress or retrogress by one commutator segment each time it passes around the armature, the condition for which is that the number of commutator segments must equal $(kp/2) \pm 1$, where $k$ is a whole number and $p$ is the number of poles.

**24. Application of two-circuit winding.** Each circuit of a two-circuit winding is made up of conductors passing under all the poles, so that no equalizers are required. Because of this, and also because only two sets

Digitized by Google

of brushes are required, this type of winding is well suited for direct-current railway motors, inasmuch as the two sets of brushes for a four-pole motor are placed 90 deg. apart so that they may easily be inspected from the car.

**25. Lap windings and wave windings.** A multiple-wound armature is sometimes said to have a **lap winding** and an armature with a two-circuit winding is said to have a **wave winding.**

**26. Dead coils.** There are generally more coils than there are slots, and each coil may have more than one turn. A coil in this case is defined as the shortest winding element between two commutator segments. It is not always possible to put a proper two-circuit winding into a given armature. A 110-volt, four-pole machine, with forty-nine slots, forty-nine coils, and two conductors per slot, may have a two-circuit winding because it fulfills the condition that $49 = (24\ p/2) + 1$; when wound for 220 volts, however, four conductors per slot are required, and the number of coils is $98 = (49\ p/2) \pm 0$, which will not give a two-circuit winding. In such a case, one coil, called a dead coil, is not connected into the winding, its two ends being taped so as to completely insulate the coil. The machine, therefore, may have a two-circuit winding with ninety-seven active coils and ninety-seven commutator segments.

**27. Turbo-generator windings.** In turbo-generators the conductors are long and move at high speed, so that the voltage between adjacent commutator segments is often higher than desirable. For such machines it has been proposed to use the type of winding shown in Fig. 13, the voltage between adjacent commutator segments being that generated in one conductor. To keep the inductance of the return conductors low, it is desirable to group together return conductors in which the currents at any instant are in opposite directions.

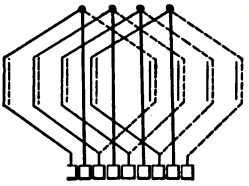

FIG. 13.—Winding with half-turn coil.

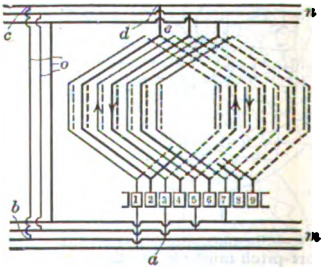

FIG. 14.—Connection of equalizer between parallel windings.

**28. Equalizer connections for turbo-generator windings.** The normal multiple-circuit doubly re-entrant duplex or multiplex windings can only be used to their full advantage when the voltage between the segments belonging to the different parallel windings is equally distributed, that is to say, the potential between segments 1 and 2 should be exactly half of the potential between segments 1 and 3; but without special means of bringing about this condition it is rather dangerous to use these windings. It may happen that the potential is very unevenly distributed between the segments, and this gives rise to very great equalizing losses over the brushes. The winding shown in Fig. 14 is a multiple-circuit doubly re-entrant duplex winding; the thin lines in the diagram indicate one of the parallel windings, the thick the other. The thin lines at the bottom of the diagram indicate the normal equalizer connections for the winding shown in thin lines, and the thick lines at the top indicate the normal equalizer connections for the winding shown in thick lines. The corresponding equalizer rings of the two parallel windings are connected through the equalizers indicated on the left of the diagram, and by means of these connections equal

Digitized by Google

division of potential between adjacent segments is ensured. In the diagram, the point which should be of the same potential as segment 3 is shown connected through two equalizer rings and the connection *o*. The potential of point *e* lies midway between the potential of segments 2 and 4, the potential of segment 3 will therefore also be midway between 2 and 4. The complete equalizing connection is denoted by the letters *a*, *b*, *o*, *c*, *d*, *e*. This winding is especially useful for turbo-machines.

**29. Shop instructions to the winding department** are generally given in the following form: For a winding such as that in Fig. 9, slot pitch 1–5, commutator pitch 1–2; which means that the two sides of the first coil shall be put in slots 1 and 5 and the commutator leads of that coil shall be connected to segments 1 and 2, where the position of segment 1 relative to that of slot 1 is fixed by the shape of the end of the coil. For a winding such as that in Fig. 12, slot pitch 1–5, and commutator pitch 1–9.*

## ARMATURE REACTIONS

**30. Cross-magnetizing effect.** Diagram *A*, Fig. 15, represents the magnetic field produced in the air-gap of a two-pole machine by the m.m.f.

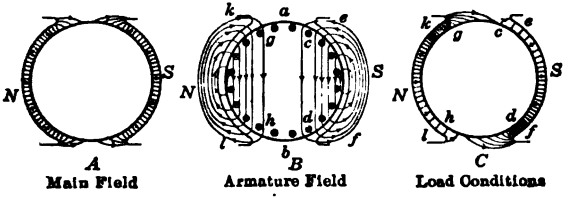

FIG. 15.—Flux distribution.

of the main exciting coils and *B* represents the magnetic field produced by the m.m.f. of the armature acting alone. If each of the *Z* armature conductors carries $I_a$ amperes, then the m.m.f. between *a* and *b*, due to the armature, is equal to $ZI_a/p$ ampere-turns, and that between *c* and *d* is equal to $\psi ZI_a/p$ ampere-turns, where $\psi$ is the ratio of pole arc to pole pitch. Assuming that all reluctance is in the air-gap, half of the m.m.f. between *c* and *d* acts across the path *ce* and the other half across *fd*, so that the cross-magnetizing effect at each pole tip is

$$\frac{\psi ZI_a}{2p} \quad \text{(ampere-turns)} \quad (1)$$

for any number of poles.

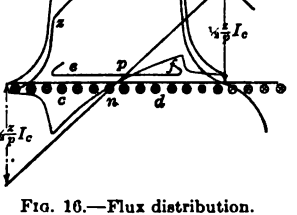

FIG. 16.—Flux distribution.

**31. Field distortion.** Diagram *C* (Fig. 15) shows the resultant magnetic field when both armature and main exciting m.m.fs. exist together; the flux density is increased at pole tips *d* and *g* and is decreased at tips *c* and *h*.

**32. Flux reduction due to cross-magnetisation.** Fig. 16 shows part of a large machine with *p* poles. Curve *D* shows the flux distribution in the air-gap due to the main exciting m.m.f. acting alone, flux density being plotted vertically. Curve *G* shows the distribution of the armature m.m.f. and curve *F* shows the resultant flux distribution when both the armature

*For further information regarding windings see: Arnold, "Die Gleichstrommaschine," Vol. I and II; S. P. Thompson, "Dynamo-electric Machinery," Vol. I; Hobart and Ellis "Armature Construction."

Digitized by Google

and the main exciting m.m.fs. exist together. Since the armature teeth are saturated at normal flux densities, the increase in flux density at $f$ is less than the decrease at $e$, so that the total flux per pole is diminished by the cross-magnetising effect of the armature.

**33. Demagnetising effect.** Fig. 17 shows the magnetic field produced by the m.m.f. of the armature when the brushes are shifted through an angle

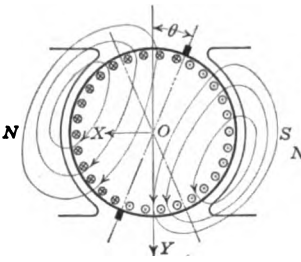

FIG. 17.

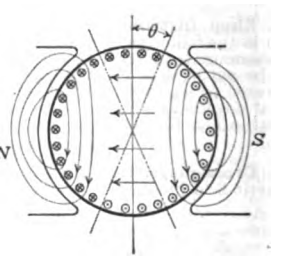

FIG. 18.

FIGS. 17 AND 18.—Demagnetising and cross magnetising effect.

$\theta$ so as to improve commutation (Par. 47). The armature field is no longer at right angles to the main field, but may be considered as the resultant of two components, one in the direction $OY$, called the cross-magnetising component, the effect of which is discussed in the last paragraph, and the other in the direction $OX$, which is called the demagnetising component because it is directly opposed to the main field. Fig. 18 shows the armature divided so as to produce these two components, and it may be seen that the demagnetising ampere-turns per pair of poles are

$$\left(\frac{ZI_c}{p}\right) \times \frac{2\theta}{180} \quad \text{(ampere-turns)} \quad (2)$$

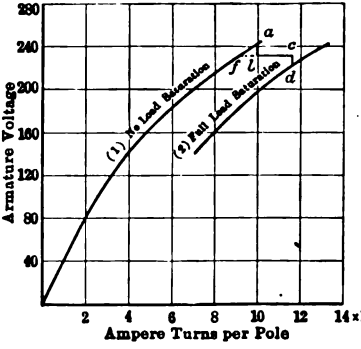

FIG. 19.

where $2\theta/180$ is generally about 0.2. Therefore the demagnetising ampere-turns per pole are

$$0.1\left(\frac{ZI_c}{p}\right) \text{(ampere-turns)} \quad (3)$$

**34. No-load and full-load saturation curves.** Curve 1, Fig. 19, shows the no-load saturation curve of a direct-current generator. When full load is put on the generator there is a decrease in flux and therefore a drop in voltage $ab$ due to the armature cross-magnetising effect (Par. 32). A further voltage drop due to the armature demagnetising effect is counter-balanced by an increase in excitation of $bc = 0.1\ (ZI_c)/p$; also a portion $cd$ of the generated e.m.f. is required in overcoming the internal resistance of the machine. With an excitation of 10,000 ampere-turns, the voltage at no load and normal speed equals 240 volts. At full load, with the same excitation, the terminal voltage equals 196 volts. In order that the full-load voltage may be the same as that at no load, the number of ampere-turns per pole which must be supplied by the series field is $(13{,}400 - 10{,}000) = 3{,}400$ ampere-turns.

Digitized by Google

**35. Relative strength of main exciting and armature magneto-motive forces.** Inspection of Fig. 16 will show that, if the armature current have such a value that the cross ampere-turns at the pole tips, namely $\frac{1}{2}ZI_c/2p$, becomes equal to the exciting ampere-turns for tooth and gap, then the flux density will be zero under the pole tip toward which the brushes have been shifted (Par. 31). The quantity $ZI_c/2p$ is the number of armature ampere-turns per pole. The exciting ampere-turns per pole for tooth and gap are seldom less than 1.2 times the armature ampere-turns per pole for a machine which must operate without sparking up to 25 per cent. overload, and which has a series field to counteract the demagnetizing effect of armature reaction. For a machine such as a shunt motor, which has no series field, the exciting ampere-turns for gap and tooth should not be less than 1.5 times the armature ampere-turns per pole.

## COMMUTATION

**36. Resistance commutation.** Fig. 20 shows part of a machine with a full-pitch double-layer multiple winding, two conductors per slot, and with coils $M$ undergoing commutation. The current in coils $M$ is reversed as the armature moves and the brushes change from segments 1 and 5 to segments 2 and 6. If the brush contact resistance is large compared with the resistance and self induction of coil $M$ then, in diagram $B$, the current $2I_c$

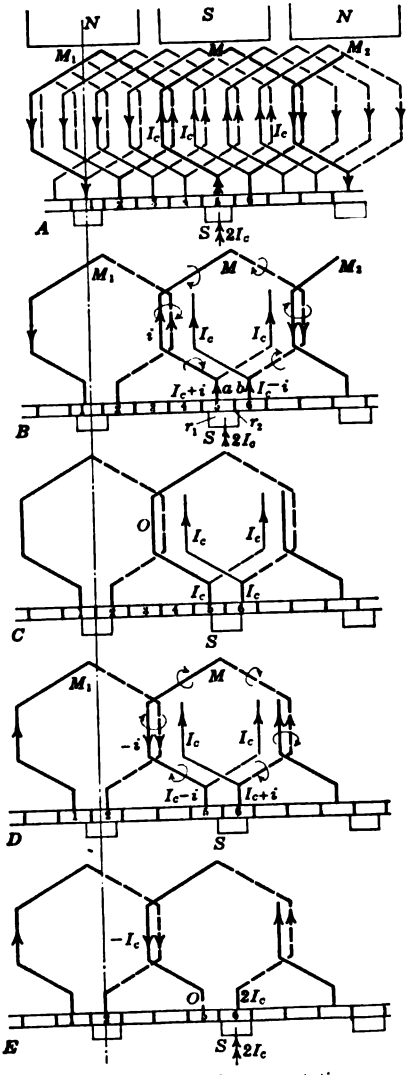

FIG. 20.—Stages in commutation.

Digitized by Google

divides into two parts which are proportional to the areas of contact between the brush and segments 5 and 6 respectively, and the current density is uniform across the brush surface. In diagram *C* the two contact areas are equal; there is no tendency for current to pass round coil *M*, and the current density is again uniform across the brush surface. In diagram *D* the contact area between the brush and segment 5 is small while that between the brush and segment 6 is large; the larger part of the current therefore enters at segment 6 and the current in coil *M* is reversed, while the current $2I_c$ again divides into two parts which are proportional to the contact areas between the brush and the two commutator segments, and the current density is still uniform across the brush surface.

**37. Perfect commutation** is defined as such a change of current in the coil being commutated that the current density over the brush contact surface is constant and uniform.

**38. The brush contact resistance** depends on the brush material and, for carbon brushes, it decreases with increase of current density as shown in Fig. 21. The contact resistance with current flowing from commutator to brush is somewhat higher than with current flowing from brush to commutator.

**39. Change of contact resistance with temperature.** If the current density in a brush contact be suddenly increased, the contact resistance does not immediately decrease to the value given in Fig. 21, but gradually decreases as the temperature of the contact increases, and reaches a constant value after about 20 min. This explains why a machine will carry a considerable overload for a short time without sparking, whereas, if the overload be maintained, the machine will begin to spark as the brush temperature increases and the contact resistance decreases.

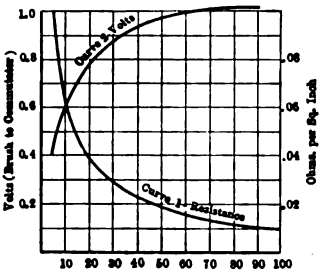

FIG. 21.—Brush contact resistance.

**40. Current density in the brushes.** For sparkless commutation, (1) the current density in the brush tip must not become infinite, and (2) the average amount of energy expended at the brush contact must be limited. For machines required to operate without sparking up to 25 per cent. overload, a rate of energy dissipation of 35 watts per sq. in. (5.5 watts per sq. cm.) may be allowed at full-load, so that the permissible current density depends upon the voltage drop across the brush contact. The better the commutation, the more nearly uniform is the current density in the brush contact, and the higher the average density which may be allowed.

**41. Current density in the brush tip.** The effect of coil resistance may generally be neglected, but that of self-induction must be considered. The e.m.f. of self-induction and mutual induction of coil *M* (Fig. 20) opposes the change of current in that coil, so that, in diagram *C*, at the end of half of the period of commutation, the current in the coils *M* has not become zero. When it does become zero, some time later, and the currents entering segments 5 and 6 are equal, the contact area with segment 5 is smaller than with segment 6 and the current density in the brush tip *S* is greater than normal. It may be shown theoretically that the tip density at the end of commutation becomes infinite* when $RT_c/(L+M)$ is less than unity,

where $R$ is the resistance of the brush contact in ohms,
$T_c$ is the time of commutation in seconds,
$L$ is the coefficient of self-induction in henrys of one coil $M$,
and $M$ is the coefficient of mutual induction in henrys between coil $M$ and coils $M_1$ and $M_2$.

* Reid, on "Direct-current Commutation," *Trans.* A. I. E E., Vol. XXIV.

Digitized by Google

**43. Copper leaf brushes** can carry 150 amp. per sq. in. (23 amp. per sq. cm.) with a drop of 0.3 volt at the contact.

**Carbon brushes** can carry 35 watts per sq. in. (5.5 watts per sq. cm.), Par. **40**, for example 35 amp. per sq. in. (5.5 amp. per sq. cm.) with a drop of 1.0 volts at the contact.

**43. Average reactance voltage.** The criterion for sparkless commutation is, then (Par. 41), that $RT_c/(L+M)$ shall be greater than unity, or that

$$2I_cR > \frac{2I_c}{T_c}(L+M) \qquad (4)$$

where $2I_c$ is the current entering the brush (Fig. 20). The latter quantity is called the average reactance voltage and the former is the voltage drop across one brush contact. It will be found that the higher the contact resistance and the lower the reactance voltage, the better is the commutation.

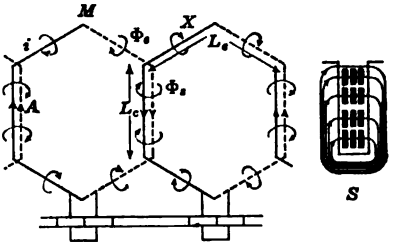

FIG. 22.

Fig. 22 shows the magnetic field encircling the short-circuited coils of a full-pitch multiple winding. The reluctance of the magnetic path may readily be calculated from which the value of the flux per unit current and $L+M$, the coefficient of self and mutual induction, are obtained. Deep slots decrease the reluctance of the magnetic path (for the same cross-section of conductor) and increase the reactance voltage, therefore they should be avoided if possible.

**44. Effect of type of winding on reactance voltage.** In the **short-pitch winding** shown in Fig. 11, the conductors undergoing commutation lie in different slots, and the reluctance of the magnetic path around the coils is greater, and the coefficient of mutual induction smaller, than in a **full-pitch winding.** The use of a short-pitch winding therefore lowers the reactance voltage and improves commutation, but, as shown in Fig. 11, it also reduces the effective interpolar space by the angle $\theta$.

In the **two-circuit winding** with one set of positive and one set of negative brushes, shown in Fig. 12, each brush short-circuits $p/2$ coils in series, so that the reactance voltage is $p/2$ times that of a **multiple winding.** When, however, the number of brush sets is the same as the number of poles, there is a short commutation path around one coil and the commutation is improved.

**45. Reactance voltage formula.** Approximate results may be obtained by use of the following formula for the average reactance voltage.*

$$E_r = kS(\text{r.p.m.})I_c L_c T^2 \left(\frac{\text{poles}}{\text{paths}}\right) 10^{-8} \qquad \text{(volts)} \qquad (5)$$

where $S$ is the number of commutator segments,
r.p.m. is the speed of the machine in rev. per min.,
$I_c$ is the current in each armature conductor,
$L_c$ is the frame length in inches (see Fig. 38),
$T$ is the number of turns per coil between segments,

$\left(\frac{\text{poles}}{\text{paths}}\right)$ = 1 for multiple windings and $p/2$ for two-circuit windings,

$k$ = 1.6 for two-circuit windings and for full-pitch multiple windings, and

$k$ = 0.93 for short-pitch multiple windings.

Deep slots increase the reactance voltage above this value.

* Gray. "Electrical Machine Design," p. 84.

Digitized by Google

**46. Effect of brush arc.** An increase in the brush arc has no effect on the reactance voltage because, while it increases the number of coils in series at short circuit, it decreases the time of commutation in the same ratio, and the reactance voltage remains unchanged. On the other hand, a wide arc may cause sparking by starting commutation in the coils before they are in a reversing field, or by keeping them short-circuited until they are in too strong a field. To minimize this trouble make the proportions such that,

$$\text{brush arc} < \left(\frac{\text{pole pitch}}{12}\right) \times \left(\frac{\text{commutator diameter}}{\text{armature diameter}}\right) \qquad (6)$$

where all dimensions are in inches. Furthermore, the brush should not cover more than three commutator segments except in machines of low reactance voltage, otherwise there will be large circulating currents in the brush face.

**47. Shifting of brushes.** To improve commutation, the brushes are shifted from the neutral position, so that the short-circuited coils are in a magnetic field and an e.m.f. ($E_s$) is generated in them which opposes the reactance voltage and improves commutation. As the current in the machine increases, the reactance voltage increases with it. To have perfect commutation at all loads, the voltage $E_s$ must maintain an unvarying ratio to the current. This is only possible when the distance by which the brushes are moved from the neutral position increases as the current increases. Modern machines must operate from no load to 25 per cent. overload without sparking and without shifting of the brushes during operation. In these machines the brushes are permanently shifted (at the time of erection) from the neutral position until the voltage $E_s$ is so large that sparking takes place at no load.

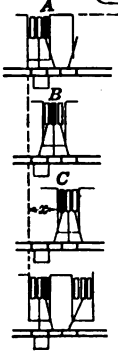

FIG. 23.—Commutation with several coils per slot.

**48. Number of slots per pole.** Fig. 23 shows three of the stages in the commutation of a machine with six coil sides per slot. The commutator segments are evenly spaced while the coils, being in slots, are not. Between the instant when the brush breaks contact with coil $A$, and the instant it breaks with coil $C$, the slot has moved through a distance $x$, so that if the magnetic field in which the coils are commutated is suitable for coil $A$, it is too strong for coil $C$, and the latter will therefore be badly commutated, every third commutator segment being blackened. The distance $x$ is equal to the slot pitch minus the width of one commutator segment. To minimize this trouble, a machine should have more than twelve slots per pole. Large machines have generally more than fourteen slots per pole.

**49. Limits of reactance voltage.** Experience shows that when the following conditions are fulfilled, namely:

(1) Number of slots per pole is greater than twelve,

(2) Brush arc is less than one-twelfth of the pole pitch measured at the commutator surface,

(3) Pole arc is less than seven-tenths of the pole pitch, and

(4) Ampere-turns for air-gap and teeth are greater than 1.2 to 1.5 times the armature ampere-turns per pole (Par. **35**): then the reactance voltage calculated by Eq. 5 (Par. **45**) should be

(1) Less than seven-tenths of the voltage drop per pair of brushes, with brushes in neutral position, and

(2) Less than the full voltage drop per pair of brushes, with the brushes shifted to improve commutation.

A machine with a two-circuit winding will commutate about 20 per cent. better than would be indicated by the value of reactance voltage obtained from Eq. 5 (Par. **45**), while the commutation of a machine with a short-pitch winding will be about 30 per cent. worse than indicated, because of the reduction of the effective interpolar space (Par. **44**).

**50. Shunt, compound and series machines.** Due to armature reaction, the flux at the pole tip toward which the brushes are shifted decreases with

Digitized by Google

increase of armature current (Par. 31). This decrease is kept within reasonable limits by the use of a strong exciting field (Par. 35) and is less in a compound machine than in a shunt machine operating on constant excitation. In the series machine the main exciting m.m.f. and the armature m.m.f. increase together, and the flux at the commutating pole tip may increase or decrease, depending on the relative strength of field and armature.

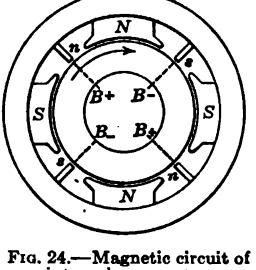

FIG. 24.—Magnetic circuit of interpole generator.

**51. Interpoles.** An interpole generator is shown diagrammatically in Fig. 24, where $n$ and $s$ are auxiliary poles which have a series winding so connected that their strength increases with the armature current. To improve commutation in a non-interpole generator, the brushes are shifted forward in the direction of motion, so that $B_+$ would come under the tip of the $N$ pole and $B_-$ under the tip of the $S$ pole. In the interpole machine the auxiliary pole $n$ is placed opposite the brush $B_+$ and the auxiliary pole $s$ opposite the brush $B_-$.

**52. Interpole excitation.** The interpole must have a m.m.f. equal and opposite to that of the cross-magnetising effect of the armature, namely, $ZI_a/2p$ ampere-turns per pole (Par. 30) and, in addition, a m.m.f. which can send across the gap a flux large enough to generate in the short-circuited coil an e.m.f. equal and opposite to the reactance voltage. In order that the interpole flux may be always proportional to the current, the interpole magnetic circuit must not be allowed to become saturated.

**53. The effective interpole arc** is represented by the expression $W_{ip}+2\delta$ (see Fig. 25) and should be of such proportions that while the current in a conductor is being commutated, the slot carrying that conductor is in the interpole field. The distance moved by the coil $A$ (Fig. 23) while short-circuited equals the brush arc multiplied by the armature diameter and divided by the commutator diameter and the effective interpole arc must exceed this by the distance $x$ (Fig. 23).

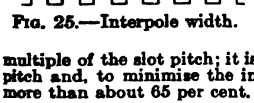

FIG. 25.—Interpole width.

**54. The reluctance of the interpole air-gap** should vary as little as possible for different positions of the armature, otherwise the interpole field will be pulsating. The effective interpole arc should therefore be a multiple of the slot pitch; it is generally made about 15 per cent. of the pole pitch and, to minimise the interpole leakage flux, the main pole arc is not more than about 65 per cent. of the pole pitch.

**55. The axial length of the interpole** in inches is given by the formula,*

$$L = \frac{24 \times \text{core length in inches} \times \text{amp. cond. per in.}}{\text{interpole gap density in lines per sq. in.}} \qquad (7)$$

The ampere-conductors per in. (Par. 59) seldom exceed 900, and, with an interpole gap density of 45,000 lines per sq. in. (7,000 lines per sq. cm.), the interpole circuit will not be saturated up to 50 per cent. overload; the interpole length, therefore, need not exceed half the frame length, if there are as many interpoles as there are main poles and if the overloads do not exceed 50 per cent.

**56. The interpole ampere-turns per pole** for a newly designed machine are usually made equal to 1.4 times the armature ampere-turns per pole (Par. 52). This is generally too large, so adjustment must be made after the machine is erected.

**57. Flashing over** is generally caused by a sudden change of load. Fig. 26 shows a representation of the armature cross-field in a loaded machine. A sudden change of load alters the value of the cross-flux, and a voltage

* Gray. "Electrical Machine Design," p. 94.

Digitized by Google

proportional to the rate of change of flux is generated in coil *a*. This may increase the voltage that already exists between adjacent segments to such a value that arcing starts, and then the machine flashes over from brush to brush, particularly if the commutator is dirty. Machines with badly distorted fields and a high average voltage between commutator segments are especially likely to flash over.

**58. Compensating windings.** For such service as the operation of reversing rolling mills, the current in the motors may change suddenly from full-load value in one direction to three times full-load value in the opposite direction. For such machines the average voltage between adjacent commutator segments, which is equal to the terminal voltage divided by the number of commutator segments per pole, should not exceed

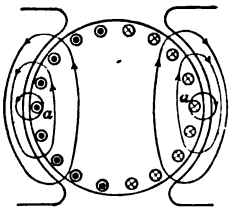

FIG. 26.

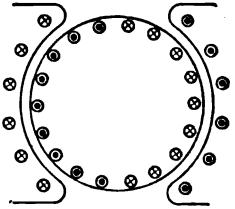

FIG. 27.

FIGS. 26 AND 27.—Armature field with and without compensating windings.

about 15, otherwise compensating windings will be required to prevent flashing over. The compensating winding is carried by the pole face, and is in series with and has the same number of ampere-turns per pole as the armature. However, the current passes in the opposite direction to that in the armature and thus, as shown in Fig. 27, the armature field is completely neutralized. For further discussion of the subject of commutation see the references below.*

## ARMATURE DESIGN

**59. Output equation.** The output of a machine is proportional to the armature volume, and the output equation is

$$D_a^2 L_c = \frac{\text{watts} \times 60.8 \times 10^7}{\text{r.p.m.} \times \mathfrak{B}_g \times q \times \Psi} \quad \text{(cu. in.)} \qquad (8)$$

where $D_a$ is the armature diameter in inches,
$L_c$ is the frame length in inches (Fig. 38),
$\mathfrak{B}_g$ is the apparent gap density in lines per sq. in.,
$\Psi$ is the per cent. enclosure ( = pole arc pole + pitch), and
$q$ is the ampere-conductors per in. ( $= ZI_c/\pi D_a$ ).

**60. The e.m.f. equation** for all types of direct-current generators is:

$$E = Z\phi_a \left(\frac{\text{r.p.m.}}{60}\right)\left(\frac{\text{poles}}{\text{paths}}\right) 10^{-8} \quad \text{(volts)} \qquad (9)$$

where $E$ is the generated voltage between terminals,
$Z$ is the total number of face conductors,
$\phi_a$ is the flux per pole which crosses the air-gap and is cut by the armature conductors,
r.p.m. is the armature speed in revolutions per min.
"paths" refer to the number of parallel circuits (electric) through the armature.

**61. Another output equation,** readily obtained from the e.m.f. equation, is given by

$$\frac{\text{watts}}{\text{r.p.m.}} = \left(\frac{ZI_a}{\text{paths}}\right)(\phi_a \times \text{poles})\frac{1}{60 \times 10^8} \qquad (10)$$

where $(ZI_a/\text{paths})$, called the **electric loading**, is the total number of ampere-conductors on the armature periphery. The larger the electric loading, the more copper and the less iron there is in the machine. The **magnetic loading**, as the quantity $(\phi_a \times \text{poles})$ is termed, is the total flux entering the armature. The larger the magnetic loading, the more iron and the less copper there is in the machine.

**62. The gap density** ($\mathfrak{B}_g$) is limited by the density at the bottom of the teeth; the greater the diameter, the less the tooth taper, and the higher the gap density for a given tooth density at the root. The relation between $\mathfrak{B}_g$ and $D_a$ is given in Fig. 28.

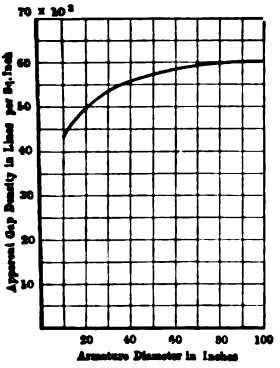

FIG. 28.

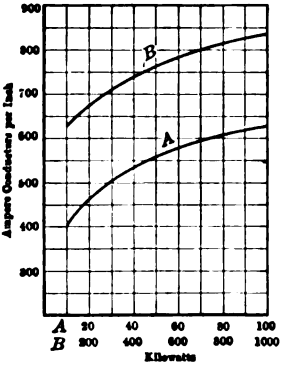

FIG. 29.

**63. The ampere-conductors per in.** ($q$) are limited by heating and by commutation. If $q$ is large, the copper section must be large and the slots deep in order to keep down the temperature, but deep slots tend to cause sparking. It is found that $q$ depends principally on the output of the machine, as shown in Fig. 29.

If the speed for a given output be increased, a smaller diameter can be used, and the peripheral velocity will not be greatly increased. Since the small machine is not so well ventilated as the large machine, see Fig. 31, the same value of $q$ should be used in each case.

**64. Relative cost factor.** A certain ratio $k$, which is equal to the magnetic loading divided by the electric loading, will give the cheapest machine. Then

$$\frac{\text{watts}}{\text{r.p.m.}} = \text{a const. (electric loading) (magnetic loading.) Par. 61.}$$

$$= \text{a const. (electric loading)}^2 \qquad (11)$$

and the relation between the watts per rev. per min. and the electric loading, given in Fig. 30, may be used in preliminary design. The value of $k$ is affected by the cost of labor and material and by the conditions of manufacture.

**65. Number of poles.** A pole of circular cross-section has the largest section for the shortest mean turn. If the pole be rectangular, then that with a square section has the largest area for the shortest mean turn. For economy in copper, the ratio of pole pitch to frame length will generally have a value between 1.1 and 1.7.

Digitized by Google

**66. The armature ampere-turns per pole** seldom exceed 7,500 in non-interpole machines. A larger number requires a long pole pitch, long end connections, a large number of exciting ampere-turns per pole, long poles, and a yoke of large diameter. For interpole machines, the main field need not be so strong relatively to the armature field as in non-interpole machines, and a reasonable limit for the armature ampere-turns per pole is 10,000.

**67. A simple procedure for armature design** is given in the following:

$ZI_c$, the number of ampere-conductors, is obtained from Fig. 30.

$q = ZI_c/\pi D_a$, the number of ampere-conductors per in., is obtained from Fig. 29.

$D_a$, the armature diameter, is next determined.

$\mathfrak{B}_g$ is obtained from Fig. 28.

$L_c$ is found by substitution in Eq. 8, Par. **59**.

$p$, the number of poles, is so chosen that the pole pitch divided by $L_c$ equals 1.1 to 1.7.

$\phi$, the flux per pole $= 0.7$ (pole pitch) $\times L_c \times \mathfrak{B}_g$, assuming the pole enclosure $= 0.7$.

$Z$, the number of armature conductors, is found from Eq. 9, Par. **60**.

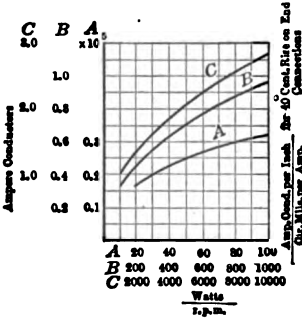

FIG. 30.

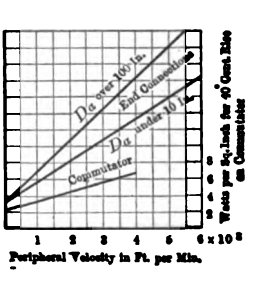

FIG. 31.

The winding is then so chosen that the reactance voltage will be below the desired limit. A two-circuit winding is the cheapest, and a winding with two turns per coil is cheaper than one with only one turn per coil.

**68. The commutator diameter** ($D_c$) is made equal to six-tenths of the armature diameter so as to have reasonably long "necks" (coil leads), but a peripheral velocity greater than 3,500 ft. per min. (1,070 m. per min.), is undesirable. One objectionable feature of the turbo-machine is that its commutator speed may run as high as 7,000 ft. per min. (2,140 m. per min.).

**69. Brush design.** The brush arc should not exceed the value $\left(\frac{\text{pole pitch}}{12}\right)\left(\frac{\text{comm. dia.}}{\text{arm. dia.}}\right)$. The volts drop per pair of brushes should be chosen to suit the reactance voltage (Par. **49**). The energy at the brush contacts is limited to 35 watts per sq. in. (5.5 per sq. cm.) (Par. **40**).

**70. Example of armature design.** It is required to determine approximate dimensions for a direct-current generator of the following rating: 400 kw., 240 volts, 1,670 amp., 200 rev. per min. The results, determined in consecutive order, are as follows:

| | |
|---|---|
| $ZI_c$, ampere-conductors, | $= 1.33 \times 10^5$ |
| $q$, ampere-conductors per in., | $= 733$ |
| $D_a$, armature diameter, | $= 58$ in. |
| $B_g$, apparent gap density, | $= 58{,}000$ lines per sq. in. |
| $L_c$, frame length, | $= 12$ in. |

Digitized by Google

| | | | |
|---|---|---|---|
| $p$, poles, | | = 10 | |
| $\tau$, pole pitch, | | = 18.2 in. | |
| $\phi$, flux per pole, | | $= 8.8 \times 10^6$ | |
| $Z$, total face conductors, | = 164 | = 820 | = 820 |
| Winding, | 1-turn ser. | 2-turn mult. short pitch | 1-turn mult. short pitch |
| $S$, commutator segments, | = 82 | = 205 | = 410 |
| $EV$, reactance voltage, | = 13 | = 3.1 | = 1.5 |
| $D_a$, commutator diameter, | | | = 35 in. |
| Brush arc, | | | = 0.91 in. |
| Volts per pair of brushes, | | | = 2 |
| Amp. per sq. in. brush contact, | | | = 35 |
| Brush length, | | | = 10.5 in. |
| $F$, commutator face, | | | = 13 in. |

If the winding were series, or two-turn multiple, the reactance voltage would be too high and interpoles would be required.

Comparative designs should be worked out with both larger and smaller armature diameters and with different numbers of poles; then a choice should be made, and the design completed as below.

The final or **detailed design** is worked out in the following order. The probable number of total face conductors is 820, from the preliminary design. The number of slots per pole should be greater than fourteen and the total number of slots greater than 140; the nearest number of slots that will give an even number of conductors per slot is 200. Therefore

| | |
|---|---|
| Slots | = 200 |
| Conductors per slot | = 4 |
| Coils | = 400 |
| Commutator segments | = 400 |
| Winding | 1-turn multiple |

Ampere-conductors per in. $= 167 \times 800/\pi \times 58 = 730$

$\frac{\text{Ampere-conductors per in.}}{\text{Cir. mils per amp.}} = 1.3$ for 40 deg. cent. rise, from Fig. 31.

| | |
|---|---|
| Cir. mils per amp. | = 560 |
| Amp. per conductor at full load | = 167 |
| Section of conductor | = 93,000 cir. mils = 0.073 sq. in. |

Slot opening = 0.47 × (slot pitch) in large machines
= 0.52 × (slot pitch) in small machines.

For a first approximation, therefore

Slot pitch = 0.91 in.
Slot opening = 0.43 in.
0.064 width of slot insulation (Fig. 47)
0.04 clearance between coil and core
0.326 available space for copper and conductor insulation.

Use flat strip, as in Fig. 47, with two conductors in the width of the slot; make the strip 0.14 in. wide and insulate it with half-lapped cotton tape.

Depth of conductor = 0.073/0.14 = 0.52 in.; increase this to 0.55 in. to allow for rounding of the corners.

Slot depth is found as follows:

0.55 = depth of each conductor
0.024 = insulation of each conductor
0.084 = depth of slot insulation (Fig. 47)
0.658 = depth of each insulated coil
2 = number of coils in depth of slot
1.316 = depth of coil space
0.2 = thickness of stick at top of slot
1.516 = necessary slot depth; make it 1.6 in.

The tooth flux density should now be checked to make sure that it is not too high, see Par. **123**, and the internal diameter of the armature made such that the flux density in the armature core shall not exceed 85,000 lines per sq. in.

**71. Effect of interpoles.** When interpoles are used, the reactance voltage is no longer a limiting factor in the design, so that deep slots may be used and a large amount of copper put on each inch of the periphery. For interpole machines, the value of $q$, the ampere-conductors per in., will

Digitized by Google

generally be 20 per cent. greater than given in Fig. 29. The commutating fringe under the pole tip is not used, so that the ratio of the exciting ampere-turns per pole for gap and teeth to the armature ampere-turns per pole, which is seldom less than 1.2 for non-interpole machines, is generally made about 0.8 for similar machines with interpoles. There is therefore a large saving in field copper, and in pole and yoke material.

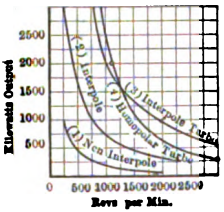

FIG. 32.—Maximum output curves.

**72. Speed limitations in design.*** If the peripheral velocity of a machine is fixed, the output can be increased only by increasing the frame length, the number of conductors, or the current per conductor, all of which increase the reactance voltage; so that, after a certain output has been reached, interpoles must be supplied or the peripheral velocity increased.† Fig. 32 shows the maximum output that can be obtained for a given speed, the peripheral velocity being taken as 6,000 ft. per min. (1,830 m. per min.) for machines of ordinary construction, and 15,000 ft. per min. (4,600 m. per min.) for turbo-machines. The high-speed turbo-machine is not too satisfactory as regards efficiency, commutation, and heating and the tendency is to gear a high-speed turbine to a moderate speed generator through a **Melville-Macalpine reduction gear.**

## FIELD DESIGN

**73. The magnetic circuit** is well shown in general in Fig. 38, where the closed dot-and-dash line indicates the complete path through one pair of poles, two air-gaps, the armature and the yoke, all in series. There are as many paths similar to this one, in a multipolar machine, as there are poles. This path, of course, is the path of the useful flux, and does not take into consideration the leakage flux.

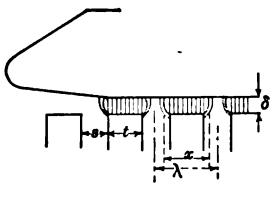

FIG. 33.

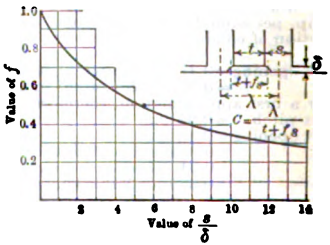

FIG. 34.

FIGS. 33 AND 34.—Fringing constant.

**74. The fringing constant.**‡ The actual air-gap area per pole equals $(\psi \tau L_c)x/\lambda$, Par. **75**, where $\lambda/x$ (Fig. 33) is the fringing constant $C$. Now $x = t + fs$ where $f$ depends on the slot width $s$ and on the air-gap clearance $\delta$ and may be obtained from Fig. 34. Then

$$C = \lambda/x = (t+s)/(t+fs) \qquad (12)$$

For the machine shown in Fig. 35:

$s/\delta = 0.43/0.3 = 1.44$
$f = 0.78$ from Fig. 34.
$C = (0.48+0.43)/(0.48+0.78\times 0.43) = 1.12$

‡ Carter, *Electrical World and Engineer*, Nov. 30, 1901; Hele-Shaw, Hay and Powell; *Jour.* of Inst. of Elec. Eng., Vol. XXXIV, p. 21.

Digitized by Google

There is a small amount of fringing at the pole tips which tends to increase the air-gap area, but this effect is counterbalanced by the effect of the increase in the air-gap clearance near the pole tips. The fringing constant for the vent ducts may be found in the same way as for the slots, but is so nearly equal to unity that the calculation is seldom made.

**75. The magnetic areas:** In Fig. 38, let

$A_y$ = the yoke area;

$A_p$ = the pole area = $W_p L_p$ for solid rectangular poles and = 0.95 $W_p L_p$ for poles built of laminations;

$A_t$ = the tooth area per pole = $(\psi N/p) t L_n$ where $L_n$, the net length of the core equals 0.9 ($L_c$ − the space taken by the ducts), $\psi$ is the ratio pole arc/pole pitch, and $N$ is the total number of teeth.

$A_c$ = the armature core area = $d_c L_n$;

$A_g$ = the apparent gap area per pole = $\psi_\tau L_c$;

$A_{ag}$ = the actual gap area per pole = $A_g/C$, where $C$ is a constant greater than unity, which takes into account the effect of the slots in reducing the gap area.

These areas are determinable, in the first instance, by dividing the total flux in a given portion of the magnetic circuit, by the allowable flux density.

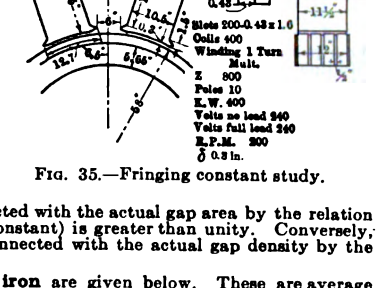

FIG. 35.—Fringing constant study.

**76. Flux density in the air-gap.** The apparent gap density which may be allowed for an armature of specified diameter is shown by the curve in Fig. 28. It will be noted that $\mathfrak{B}_g = \phi_a/A_g$, where $A_g$ is the apparent gap area per pole. The apparent gap area is connected with the actual gap area by the relation $A_g = CA_{ag}$, where $C$ (fringing constant) is greater than unity. Conversely, the apparent gap density is connected with the actual gap density by the same constant, and $B_{ag} = CB_g$.

**77. Flux densities in the iron** are given below. These are average values found in standard machines designed for continuous duty.

| | Expression for | Material of magnetic circuit | Lines per sq. in. | Lines per sq. cm. |
|---|---|---|---|---|
| $\mathfrak{B}_y$, the yoke density | $\frac{\phi_m}{2A_y}$ | cast iron.... | 40,000 | 6,200 |
| | | cast steel.... | 80,000 | 12,400 |
| $\mathfrak{B}_p$, the pole density | $\frac{\phi_m}{A_p}$ | laminations.. | 95,000 | 14,700 |
| | | cast steel.... | 90,000 | 14,000 |
| $\mathfrak{B}_t$, the apparent tooth density (maximum) | $\frac{\phi_a}{A_t}$ | laminations. | 150,000 | 23,000 |
| $\mathfrak{B}_c$, the core density | $\frac{\phi_a}{2A_c}$ | laminations. | 85,000 | 13,000 |

**78. The apparent tooth density** ($\mathfrak{B}_t$) is greater than the actual density in the teeth because, since the teeth are highly saturated at normal densities, a considerable amount of flux passes down the slots, vent ducts, and air spaces between the laminations. The relation between the apparent and the actual tooth density is given in Fig. 36, for the magnetisation curves shown in Fig. 37 and for the ratio $L_n/L_c = 0.8$.

**79. Leakage factor.** Fig. 38 shows two poles of a multipolar machine;

Digitized by Google

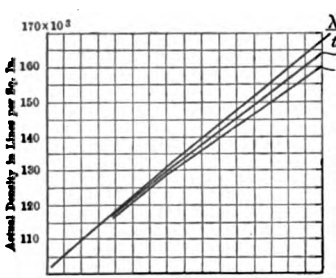

FIG. 36.—Armature tooth densities.

$\phi_m$, the total flux per pole, consists of the flux $\phi_a$ which crosses the air-gap and is cut by the armature conductors, and the leakage flux $\phi_\ell$ which crosses between the poles but does not enter the armature. The ratio $\phi_m/\phi_a$, called the leakage factor, is greater than unity; its value may be calculated with a fair degree of accuracy if the dimensions of the magnetic circuit are known, but for direct-current machines it is usual to assume a value of leakage factor and, for a first approximation, the following table may be used for the type of machine shown in Fig. 38.

| | Leakage factor |
|---|---|
| Four-pole machines up to 10 in. armature diameter.... | 1.25 |
| Multipolar machines between 10 in. and 30 in. diameter.. | 1.2 |
| Multipolar machines between 30 in. and 60 in. diameter.. | 1.18 |
| Multipolar machines greater than 60 in. diameter..... | 1.15 |

**80. Calculation of the leakage factor.*** Fig. 39 shows part of a machine with a large number of poles. The total leakage flux per pole is

$$\phi_\ell = \phi_1 + \phi_2 + \phi_3 + \phi_4 \qquad (13)$$

*The derivation of these formulæ is given in Gray, "Electrical Machine Design," page 51, for other cases see Hawkins and Wallis, "The Dynamo," Vol. I, p. 471.

Digitized by Google

where

$$\phi_1 = 13k(nI)_{g+t}\ \frac{L_s h_s}{l_1} \tag{14}$$

$$\phi_2 = 19k(nI)_{g+t}\ h_s \log_{10}\left(1+\frac{\pi W_s}{2l_1}\right) \tag{15}$$

$$\phi_3 = 6.5k(nI)_{g+t}\ \frac{L_p h_p}{l_2} \tag{16}$$

$$\phi_4 = 9.5k(nI)_{g+t}\ h_p \log_{10}\left(1+\frac{\pi W_p}{2l_2}\right) \tag{17}$$

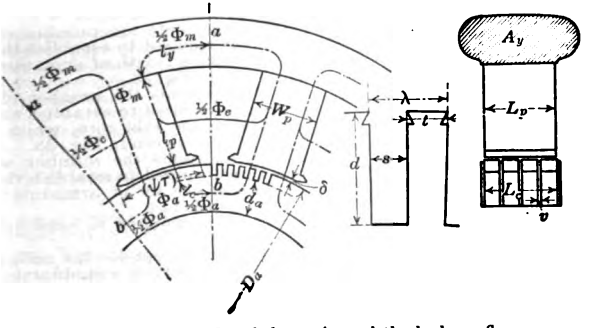

FIG. 38.—The paths of the main and the leakage fluxes.

and $k$ is equal to unity for inch units and to $1/2.54 = 0.3937$ for centimeter units. For a given value of $\phi_a$, the flux crossing the air-gap, the value of $(nI)_{g+t}$, the necessary ampere-turns per pole for gap and teeth, may be found; and, substituting this value in the above formulas, the corresponding value of $\phi_s$ may be found. The leakage factor $= 1 + \phi_s/\phi_a$.

**81. Calculation of field ampere-turns per pole.** The total ampere-turns per pole required to establish the necessary flux in the magnetic circuit may be analyzed into a series of components. The natural subdivision follows the several different members or elements which go to make up the complete circuit. These would include the yokes, the field cores, the air-gaps, the armature teeth and the armature core. Since the field poles are structurally duplicates of each other, except where interpoles are used, it is natural to confine the calculations of required ampere-turns to a single field pole. Fig. 40 shows the unit magnetic circuit for a multipolar machine, or that part of the total magnetic structure which corresponds to one field pole and simply needs repeated application to build up the whole structure. This unit magnetic circuit comprises one complete field core, one complete air-gap, one complete group of armature teeth under a single pole

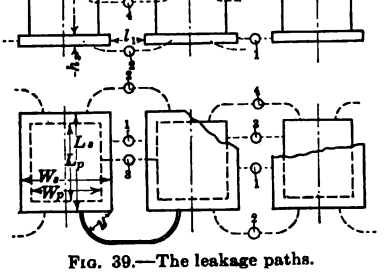

FIG. 39.—The leakage paths.

Digitized by Google

face, two half-yokes in parallel and two half-armature cores in parallel. The total number of ampere-turns, at no load, may be expressed as

$$nI = (nI)_y + (nI)_c + (nI)_p + (nI)_t + (nI)_g \qquad (18)$$

where the several quantities in the formula are as follows:

$(nI)_y$ represents the number of ampere-turns required to establish the flux $\phi_m/2$ through a length of yoke equal to $l_y$ in Fig. 38; this length is one-half the total length of the yoke circuit from pole to pole. In a single-yoke machine, such as the horse-shoe bipolar type, with two field coils, the full value of flux, or $\phi_m$, should be assumed instead of $\phi_m/2$.

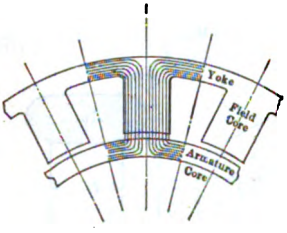

FIG. 40.—Unit magnetic circuit of multipolar machine.

$(nI)_c$ represents the number of ampere-turns required to establish the flux $\phi_a/2$ through a length of armature core equal to $l_c$ in Fig. 38.

$(nI)_p$ represents the number of ampere-turns required to establish the flux $\phi_m$ through the field core, which has a length of $l_p$ as shown in Fig. 38.

$(nI)_t$ represents the number of ampere-turns required to establish the flux $\phi_a$ through one set of armature teeth under one pole face.

$(nI)_g$ represents the number of ampere-turns required to establish the flux $\phi_a$ through one air-gap.

The calculation of ampere-turns in each case, except for the air-gap, is carried out by taking different values of flux density $\mathfrak{B}$ and obtaining the proper value of ampere-turns per in. from the curves in Fig. 37; the latter is then multiplied in each instance by the length of the corresponding portion of the magnetic circuit, in inches.

The required number of ampere-turns for the air-gap, in terms of inch units, is given by

$$(nI)_g = \frac{C\,\mathfrak{B}_g\,\delta}{3.20} \qquad (19)$$

and in terms of centimeter units, by

$$(nI)_g = \frac{C\,\mathfrak{B}_g\,\delta}{1.26} \qquad (20)$$

The quantity $C$ is the fringing constant (Par. **75**).

**83. Excitation for tapered teeth.** When the armature teeth are tapered, the flux density is not uniform throughout the total depth of the tooth. The tooth length must therefore be divided into a number of short lengths, the flux density and the corresponding ampere-turns per in. length found in each case, and the average value multiplied by the tooth length to give $(nI)_t$. This process can be shortened by use of the series of curves shown in Fig. 41; if $k$, the ratio between the actual flux densities at the bottom and at the top of the tooth, is known, the average ampere-turns per in. can be found directly.

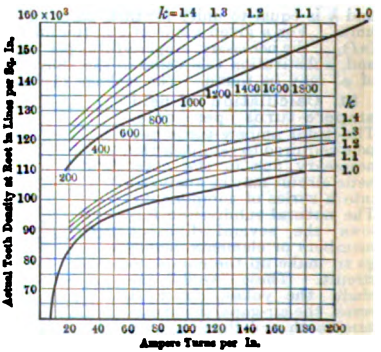

FIG. 41.—Magnetization curves for tapered teeth.

**83. Calculation of the no-load saturation curve.** Taking the example of the ten-pole machine shown in Fig. 35, the following calculations must be carried out in order to obtain a series of points from which to plot the no-load saturation curve.

$L_a$ = the net axial length of armature core = 0.9 (12 − 3 × 0.5) = 9.45 in.
$A_y$ = the yoke area = 136 sq. in.

Digitized by Google

$A_p$ = the pole area = $0.95 \times 10.5 \times 11.5 = 114$ sq. in.

$A_t$ = the minimum tooth area per pole = $0.7 \times \frac{200}{10} \times 0.43 \times 9.45 = 57$ sq. in.

$A_c$ = the core area = $5.65 \times 9.45 = 53.5$ sq. in.

$A_g$ = the apparent gap area = $12.7 \times 12 = 153$ sq. in.

$C$ = the fringing constant = 1.12 from Par. **74**.

$\phi_u$ = the useful flux per pole = $\frac{240 \times 60 \times 10 \times 10^8}{800 \times 200 \times 10}$ from Par. **60**.
$= 9 \times 10^6$

The leakage factor = 1.16 from Par. **79**.

$\phi_m$ = the total flux per pole = $10.5 \times 10^6$

$\mathfrak{G}_y$ = the yoke density = 39,000 lines per sq. in.

$\mathfrak{G}_p$ = the pole density = 93,000 lines per sq. in.

$\mathfrak{G}_t$ = the apparent tooth density = 158,000 lines per sq. in.

The actual tooth density (Fig. 36) = 150,000 lines per sq. in.

$\mathfrak{G}_c$ = the core density = 84,000 lines per sq. in.

$\mathfrak{G}_g$ = the apparent gap density = 59,000 lines per sq. in.

$nI_y$ = for a cast-iron yoke = $75 \times 13 = 980$ ampere-turns.

$nI_y$ = for steel punchings = $40 \times 15 = 600$ ampere-turns.

$nI_t$ = = $1300 \times 1.6 = 2080$ ampere-turns, from Fig. 41.

$nI_c$ = = $20 \times 6.5 = 130$ ampere-turns

$nI_g = \frac{1.12 \times 59{,}000 \times 0.3}{3.2} = 6{,}200$ ampere-turns.

The total ampere-turns per pole at 240 volts = 9,990. Three more points are worked out in the same way and then plotted in curve 1, Fig. 19.

**84. The full-load saturation curve** is shown in curve 2, Fig. 19. The drop in voltage *ab* is due to the decrease in flux caused by the cross-magnetising effect of the armature, Par. **32**; the ampere-turns *bc* are required to overcome the demagnetising effect of the armature and are equal to $0.1ZI_c/p$, from Par. **33**; the voltage *cd* is that required to send full-load current through the resistance of the armature winding, the brushes and the series field coils.

**85. Calculation of cross-magnetising effect.** The method of calculating the decrease of flux due to the armature cross-magnetising effect is complicated and will be found in several standard texts.* The decrease in flux is directly proportional to the armature ampere-turns per pole; it also depends on the tooth density and on the ratio of the armature ampere-turns per pole to the exciting ampere-turns per pole for tooth and gap (Par. **35**). For a first approximation on standard machines, allowance may be made by making the distance *fc*, Fig. 19, equal to 0.3 times the armature ampere-turns per pole. In the machine shown in Fig. 35,

The armature ampere-turns per pole = $\frac{1}{2} \times \frac{800}{10} \times 167 = 6{,}700$

The demagnetising ampere-turns per pole = $0.2 \times 6{,}700$ = 1,340

The equivalent cross-magnetising ampere-turns per pole = 670

The resistance of armature and series field coils = 0.0037 ohms

The volts drop in armature and series field coils = 6.2

The volts drop per pair of brushes = 2.0

**86. The size of wire for field coils** is given by the formula

$$\text{cir. mils} = \frac{n_f I_f M}{E_f} \qquad (21)$$

where $I_f$ is the current in each field coil,
$n_f$ is the number of turns per field coil,
$M$ is the length of mean turn in inches,
$E_f$ is the voltage drop across each field coil.

Thus, for a given machine, the size of wire for the field coils is fixed as soon as the number of ampere-turns per pole and the voltage per coil have been determined.

**87. The minimum length of field coil** to give the necessary radiating surface for cooling is given by the formula*

$$L_f = \frac{n_f l_f}{1{,}000}\sqrt{\frac{\text{length of mean turn}}{\text{external periphery} \times \text{watts per sq. in.} \times d_f \times sf \times 1.27}} \qquad (22)$$

where $L_f$ is the length of the field coil in inches, Fig. 42,
$d_f$ is the depth of the field coil in inches,
$sf$ is the space factor of the winding and may be found from Fig. 43.

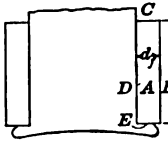

FIG. 42.—Field coil length.

The allowable watts per sq. in. of surface $B$, Fig. 42, may be found from Fig. 44.

**88. The weight of field coil** for a given machine is equal to $\sqrt{d_f}$ multiplied by a constant. The larger the value of $d_f$, the shorter the length $L_f$, the smaller the radiating surface and the lower the permissible loss in the coil. Since the section of the field coil wire is fixed (because it depends only on the ampere-turns and the voltage per coil, Par. 86), a lower permissible loss can be obtained only by the use of a smaller current $I_f$, a larger number of turns $n_f$, and therefore a more expensive coil. It must not be overlooked, however, that when $d_f$ becomes smaller and the field coil becomes cheaper, the value of $L_f$ increases and therefore the cost of the poles and the yoke increases. The most economical value for $d_f$ must be determined by trial; an average value is 2 in.

**89. Example of field system design.** The armature of a ten-pole, 240-volt no-load, 240-volt full-load, 1,670 amp., 200 r.p.m. generator is shown drawn to scale in Fig. 35; it is required to design the field system, which is not supposed to be given.

The following data are taken from Par. 88.

$\phi_m = 10.5 \times 10^6$
$\phi_g = 9 \times 10^6$
$nI_f = 2{,}080$
$\mathfrak{B}_g = 59{,}000$ lines per sq. in.

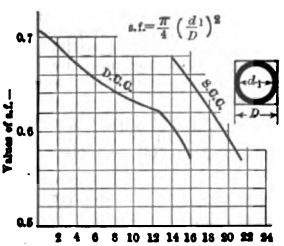

FIG. 43.—Space factor for wire.

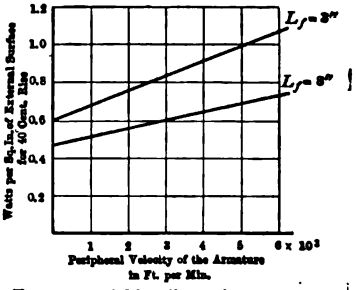

FIG. 44.—Field-coil heating constant.

**(a) Calculation of the air-gap clearance.**

$(nI)_g + (nI)_f = 1.2$ times the armature ampere-turns per pole, from Par. 85,
$= 1.2\ (800 \times 167/2 \times 10) = 8{,}100$
$(nI)_f = 2{,}080$ see above
$(nI)_g = 6{,}020$,
$C\delta = 3.2 \times 6{,}020/59{,}000$, from Par. 81,
$= 0.328$ in.,
$C = 1.12$ from Fig. 34,
$\delta = 0.29$ in. (make it 0.3 in.).

* Gray. "Electrical Machine Design," p. 66.

Digitized by Google

**(b) Calculation of approximate dimensions for the magnetic circuit.**

Assume the no-load excitation = $1.25[(nI)_g+(nI)_t]$
= 10,100 ampere-turns per pole.

Next find $L_f$ for the shunt coil from eq. 22 (Par. 87), where $d_f$ is assumed to be 2 in.; $s_f$ is assumed to be 0.6, from Fig. 43; the allowable watts per sq. in. = 0.6 from Fig. 44; the external periphery of the field coil equals 1.2 times the length of the mean turn, approximately; therefore $L_f$ = 10 in., approximately; the latter should be increased 30 per cent. to allow for the series coil.

The pole area = $\phi_m/\mathfrak{B}_p = 10.5\times10^4/95{,}000 = 112$ sq. in.

The yoke area = $\phi_m/2\mathfrak{B}_y = 10.5\times10^4/2\times40{,}000 = 132$ sq. in.

**(c) Saturation curves.** From these dimensions the magnetic circuit is drawn to scale and the no-load and the full-load saturation curves are determined and plotted. For the machine in question, the curves are given in Fig. 19.

**(d) Design of the shunt coils.** The details are as follows:

The no-load excitation = 9,990 ampere-turns per pole, Fig. 19, or Par. 88.

$E_f$, the volts per coil, equals $0.8\times240/10 = 19$ volts; this leaves 20 per cent. of the terminal voltage to be absorbed by the field rheostat.

$M$, the mean turn, equals 53 in. The external periphery equals 61 in.

The size of wire equals $9{,}990\times53/19$, from Par. 85, or 28,000 cir. mils. The proper size of wire is No. 5.5 A.W.G., a special size between Nos. 5 and 6, which has a section of 29,500 cir. mils and a diameter when insulated with double cotton of 0.19 in. When such odd sizes are not available, the coil can be made with the proper number of turns of No. 5 wire in series with the proper number of turns of No. 6, so as to have a field coil of the proper resistance.

The number of layers of wire in a 2-in. depth equals $2/0.19 = 10$.

The number of turns per layer in a 10-in. length equals $10/0.19 = 53$.

$s_f$, the number of turns per coil, equals 530.

$I_f$, the shunt current, equals $9{,}990/530 = 18.8$ amp.

The current density equals $29{,}500/18.8 = 1{,}570$ cir. mils per amp.

**(e) Design of the series coils.** The details are as follows:

| | |
|---|---|
| Excitation at full load and normal voltage | = 13,400 ampere-turns, Fig. 19. |
| Shunt excitation at normal load | = 9,990 ampere-turns. |
| Series ampere-turns per pole at full load | = 3,410 |
| Series turns per pole | = 2.5 |
| Series current = 3,410/2.5 | = 1,370 amp. |
| Current in series shunt | = 300 amp. |

The current density is taken 20 per cent. greater than in shunt coils because the series coils are better ventilated.

| | |
|---|---|
| Current density | = 1,300 cir. mils per amp. |
| Size of wire = 1,300×1,370 | = 1,780,000 cir. mils = 1.4 sq. in. |
| Resistance of 2.5 turns | = $7.4\times10^{-5}$ ohms. |
| Loss in one series coil | = $1{,}370^2\times7.4\times10^{-5} = 140$ watts. |

The permissible watts per sq. in. is taken 20 per cent. greater than in shunt coils.

| | |
|---|---|
| Watts per sq. in. | = 0.72 |
| Necessary radiating surface | = 140/0.72 = 195 sq. in. |
| Length $L_f$ of series coil | = 195/61 = 3.2 in. |
| Depth of wire = wire section/$L_f$ | = 0.45 in. |

Size of wire = 3 strips (3.2 in.×0.15 in.).

## GENERAL DESIGN AND CONSTRUCTION

**90. Type of construction for small machines.** Fig. 45 shows the type of construction generally adopted for machines up to 100 h.p. at 600 rev. per min.

**91. The armature core** ($M$ in Fig. 45) is built of laminations of sheet steel 14 mils (0.35 mm.) thick, which are separated from one another by layers of varnish and have slots $F$ punched to carry the armature coils $G$.

**92. A marking notch** is punched at one side of the key-way $K$ (Fig. 45) and these notches must line up when the punchings are assembled, to ensure that the burrs at the edges all lie in the same direction.

Digitized by Google

**93. Brass vent segments** (*P* in Fig. 45), about ¼ in. (1 cm.) wide, separate the core into sections about 3 in. (7.5 cm.) wide. The core and the vent segments are clamped between end heads *N* which carry coil supports *L* attached by arms shaped like fans. The coils are held in place against centrifugal force by steel band wires.

**94. The poles** (*B* in Fig. 45), are of circular cross-section in order to give the required area for the magnetic flux with the minimum length of mean turn of field coil *A*. They are made of forged steel and have laminated pole faces *E* made of sheet steel 25 mils (0.63 mm.) thick.

**95. End play** is provided for by making the axial length of the pole face ¼ in. (1 cm.) shorter than that of the armature core. This enables the revolving part of the machine to oscillate axially and so prevent the journals, bearings and commutator from wearing in grooves.

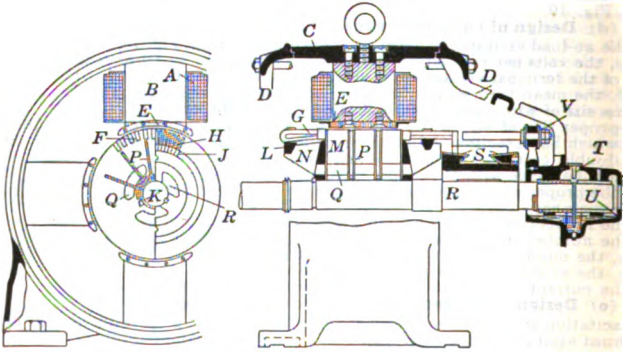

FIG. 45.—Small direct-current motor.

**96. The yoke** (*C* in Fig. 45) carries the bearing housings *D* which stiffen the whole machine. The housings can be rotated with respect to the yoke through 90 deg. or 180 deg., so that the machine may be mounted either on a wall or a ceiling. This rotation of the bearings is necessary because the machine is lubricated by **oil rings** and the **oil wells** must always be below the shaft.

**97. The commutator segments** (*J* in Fig. 45) are of hard-drawn copper and have a wearing depth of from 0.5 in. (1.25 cm.) on a 5-in. (12.5-cm.) commutator to 1.0 in. (2.5 cm.) on a 50-in. (125-cm.) commutator. The commutator shell, as the clamps and their supports are called, is provided with air passages *R* which help to keep the machine cool.

**98. The bearing construction** is shown in detail in Fig. 45. The projection *T* on the oil-hole cover keeps the oil ring from rising and resting on the bushing; the oil slingers prevent the oil from creeping along the shaft. The liner of special bearing metal is given a snug fit in the bearing shell, and can be removed when worn and another put in its place. A small overflow at *U* makes it impossible to fill the bearing too full.

**99. The brushes** are carried on studs which are insulated from the rocker arm *V*. The rocker arm is carried on a turned seat on the bearing and can be clamped in a definite position.

**100. Type of construction for large engine-type generators.** For large direct-connected engine-type units the type of construction shown in Fig. 46 is generally adopted. The **armature core** is built of segments carried by dovetails on the spider. The segments of alternate layers overlap so as to break joints and give a solid core. The **poles** are of rectangular cross-section

Digitized by Google

and are built of laminations 25 mils (0.63 mm.) thick, of the shape shown at *P*, and assembled so that the rounded pole tips point in opposite directions and a saturated tip is produced which helps commutation. The **shaft, base and bearings** are generally supplied by the engine builder, so that the commutator must be supported from the armature spider; the **brush rigging** must also be supported by the machine.

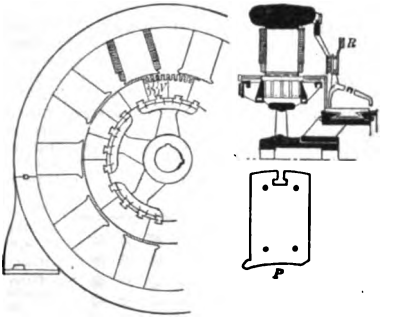

FIG. 46.—Large engine-type generator.

**101. Mechanical design.** * The **yoke** should be heavy and, in engine-type units, is often made with a large section of cast iron rather than a smaller section of cast steel; it must be stiff enough to prevent undue sagging even when there is a large unbalanced magnetic pull. The **shaft** should be stiff enough to limit the deflection to 5 per cent. of the air-gap clearance and, along with the **spider**, should have a **factor of safety** of 12 to take care of short-circuits.

**102. Unbalanced magnetic pull.** † If the armature of a machine is $x$ cm. out of centre, the flux density under the poles where the gaps are smallest will be greater than under the poles where the gaps are largest, and the pull on one side of the machine will be greater than on the other by an amount

$$kS\mathfrak{G}^2\frac{x}{\delta} \qquad (23)$$

where $\mathfrak{G}$ is the effective gap density,

$S = \pi D_a L_c$, the total armature-core surface,

$x$ = armature displacement,

$\delta$ = length of air-gap,

$k = \dfrac{1}{7.2\times10^7}$ if inch units are used and the pull is in pounds,

$k = \dfrac{1}{2.47\times10^7}$ if centimeter units are used and the pull is in kilograms.

The above formula holds for a two-circuit winding; if a multiple winding is used, the e.m.fs. in the different paths will be unequal, and circulating currents will flow tending to keep the flux densities under the poles nearly equal, so that the pull will be less than that given by the formula.

## INSULATION

**103. General requirements.** A good insulator for electrical machinery must have high dielectric strength and high electrical resistance, should be tough and flexible, and should not be affected by heat, vibration, or other operating conditions.

**104. The insulating materials generally used** for revolving machinery are as follows:

(a) **Micanite,** which is easily bruised and should be protected by a tougher material.

(b) **Varnished cloth,** which must be carefully handled to prevent cracking or scraping of the varnish film.

(c) **Paper,** which is chosen for its toughness and should be baked dry when tested.

† Behrend, B. A. *Trans.* A. I. E. E., Vol. XVII, p. 617.

Digitized by Google

(d) **Cotton tape**, which is used to insulate copper strip of large section.

(e) **Cotton covering** is used in one, two or three layers, and has the thickness given in Sec. 5, when applied to round wire. Small strip copper is generally double-cotton-covered, and the total thickness of insulation (two sides) varies from about 14 mils on the smaller sizes to about 20 mils on sizes more than ¼ in. thick.

(f) **Impregnating compound** must be used at a temperature lower than 120 deg. cent., which is the breakdown temperature of cotton. It should have as little chemical action as possible on copper, iron and insulating materials.

(g) **Elastic finishing varnish** should have a hard skin when dry and should be proof against oil, water, acids, and alkalies.

**105. The limiting temperature*** for cellulose materials is about 120 deg. cent., but the operating temperature should not exceed about 90 deg. cent. When subjected to higher temperatures for long periods, the material becomes dry and brittle, and pulverizes under vibration. When mica, asbestos, enamels and special gums can be prepared in such a manner that they are tough and flexible and do not become brittle at high temperatures, then the operating temperature limit may be increased.

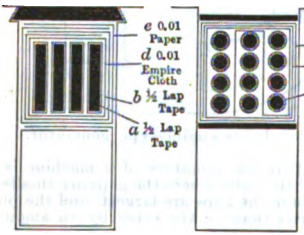

FIG. 47. FIG. 48.

FIGS. 47 AND 48.—Armature slot insulation.

**106. Insulation of adjacent conductors in a slot.** The voltage between adjacent commutator segments seldom exceeds 20 volts, so that cotton tape is sufficient insulation between adjacent coils in a slot. When the individual coils are made of a number of turns of round double-cotton-covered wire, it is advisable to put extra insulation between them as shown in Fig. 48, because the cotton covering may become damaged when the coils are squeezed together to get them into a slot.

**107. Example of 240-volt armature insulation.** The winding is to be of the double-layer multiple type with two turns per coil and four coils or eight conductors per slot. The conductors are to be of strip copper wound on edge. A section through the slot and insulation is shown in Fig. 47, and the various operations are as follows:

(*a*) After the copper has been bent to shape, tape it all over with one layer of half-lapped cotton tape 6 mils (0.15 mm.) thick. This forms the insulation between adjacent conductors in the same slot.

(*b*) Tape together the two coils that form one group, with one layer of half-lapped cotton tape 6 mils (0.15 mm.) thick. This forms the end-connection insulation and also part of the slot insulation.

(*c*) Bake the coil in a vacuum tank at 100 deg. cent. so as to expel all moisture, then dip it in a tank of impregnating compound at 120 deg. cent. and leave it there long enough to become saturated with compound.

(*d*) Place one turn of empire cloth 10 mils (0.25 mm.) thick on the slot portion of the coil and lap it over as shown at *d*. This empire cloth coil should project 0.75 in. (2 cm.) from each end of the core.

(*e*) Place one turn of paper 10 mils (0.25 mm.) thick on the slot portion of the coil and lap it over as shown at *e*. This paper also should project 0.75 in. (2 cm.) beyond the core at each end. It is not placed on the coil for insulating purposes, but to protect the other insulation which is likely otherwise to become damaged when the coils are being placed in the slots.

(*f*) Heat the coil to 100 deg. cent. and then press the slot portion to shape while hot. The heat softens the compound and the pressure forces out the excess of compound. The coil is allowed to cool under pressure and comes out of the press with such a shape and size that it slips easily into the slot.

(*g*) Dip the ends of the coil into elastic finishing varnish.

**108. Example of 550-volt insulation for a railway motor armature.** The winding is of the double-layer, two-circuit type with four turns per coil of double-cotton-covered wire and six coils or twenty-four conductors per slot. A cross-section through the slot and insulation is shown in Fig. 48. The various operations are as follows:

(*a*) The cotton-covered wire is treated with enamel to increase its heat-resisting properties and is then bent to shape.

(*b*) A group of three coils are placed together and a wrapping of mica cloth, made of 5-mil (0.13-mm.) mica and 5-mil (0.13-mm.) cloth is placed on the slot portion of the coil to form the insulation between coils and also between the coil group and the sides of the slot.

(*c*) The end leads of each coil have to pass all the other turns of the coil and are insulated with a stocking of cotton, different colors being used for the three coils in a group so that the position of each coil may be easily determined when the winding is being connected to the commutator.

(*d*) The group of three coils is taped on the ends with half-lapped cotton tape 6 mils (0.15 mm.) thick, which tape is allowed to overlap the slot insulation for 0.5 in. (1.3 cm.) so as to bind it in place.

(*e*) The group of coils is completely taped with one layer of half-lapped cotton tape 6 mils (0.15 mm.) thick.

(*f*) The top and the bottom layers of the winding are separated from one another at the ends by a layer of canvas 30 mils (0.75 mm.) thick and in the slot by a layer of fibre 30 mils (0.75 mm.) thick.

(*g*) After being wound, the armature is impregnated with compound and is finally painted with elastic finishing varnish.

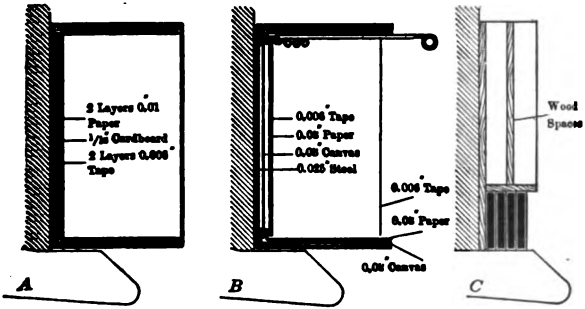

FIG. 49.—Field coil insulation.

**109. Field coil insulation.** Three examples are shown in Fig. 49. The coils, after being wound and taped, are baked in a vacuum tank and then impregnated with compound. This compound is a better insulator than the air which it replaces; it is also a better conductor of heat.

**110. Ventilated field coils,** as shown at *C* in Fig. 49, are insulated with wooden spacing pieces about 0.5 in. (1.3 cm.) thick. The coils are made self-supporting by being impregnated with solid compound at about 120 deg. cent. The insulation on the individual turns of the series coil consists of one layer of half-lapped cotton tape 6 mils (0.15 mm.) thick.

**111. Fire-proof field coils** for railway motors have been made with strip copper wound on edge, with asbestos insulation between layers. The coils are brought to a red heat to expel the binding material in the asbestos fabric and then placed in a metal case lined with asbestos and sheet mica.

**112. Commutator segments** are insulated from one another by micanite about 30 mils (0.75 mm.) thick, strips of uniform thickness being used and the copper segments tapered to suit. The mica must be one of the soft varieties (Sec. 4) so that it will wear equally with the copper segments.

Digitized by Google

The segments of copper and mica are assembled together in an external press ring, are next heated to soften the binding material in the micanite, and are then drawn tightly together. The *V*-grooves shown in Fig. 45 are then turned and the segments clamped tightly by the *V*-cones, from which they are insulated by mica cones $\frac{1}{16}$ in. (1.6 mm.) thick.

**113. Potential stresses due to switching.** A conductor conveying a current is surrounded by a magnetic field. If the circuit be suddenly opened, the flux decreases rapidly and an e.m.f. is induced in the circuit. In the case of shunt field coils with many turns, this e.m.f. may be excessive and must be provided against as described in Par. **245** and **249**. This flux due to the field coils also threads the armature, and the sudden change of flux may increase the e.m.f. per coil enough to cause flashing over between segments or to break down the insulation between adjacent coils in the same slot. This latter trouble may also be caused by a sudden change of load (see Par. **57**).

**114.** If, due to switching, any point in a coil be suddenly raised by a potential of $E$ volts, the potential of the whole winding will gradually rise; but, as this requires a definite though very short interval, the potential difference across the first few turns of the coil is approximately equal to $E$ and may be large enough to break down the insulation between adjacent turns near the terminals.

**115. Puncture test.** To make sure that there is enough insulation between the conductors and the core, and that this insulation has not been damaged in handling, all new machines are subjected to a puncture test before they are shipped, that is, a high voltage is applied between the conductors and the core for 1 min. If the insulation does not break down, it is assumed to be ample. The values of puncture voltage recommended by the Standards Committee of the American Institute of Electrical Engineers may be found in Sec. 24. For further information on insulation see footnote.*

## COOLING AND VENTILATION

**116. Heat transfers.** The losses in an electrical machine are transformed into heat, causing a rise of temperature at the source of loss. Heat is transmitted in general by three methods, namely, conduction, convection and radiation. In order that a flow of heat may take place, there must be a difference of temperature, and heat flows in the direction of diminishing temperature. Thus the highest temperature, or "hot spot," in an electrical machine, is at the seat of loss; the temperature falls in the direction in which the heat flows, and becomes a minimum at the point or points where the heat leaves the machine. The temperature becomes stationary when the rate at which heat is generated is equal to the rate at which it is conducted away.

**117. Heating and cooling curves.** The rate at which heat is dissipated depends on the difference between the temperature of the machine and that of the surrounding air. During a brief interval after starting under load, this temperature difference is small, very little heat is dissipated, and the temperature rises rapidly. As the temperature increases, more of the heat is dissipated, and the temperature rises more slowly. The heating and cooling curves of a continuous-current motor are given in Fig. 50, the cooling curve being the reciprocal of the heating curve.

**118. General effect of densities and speed.** The lower the flux and the current densities, the larger will be the mass of material in the machine for a given loss, and the longer the time taken to reach the final temperature. Slow-speed machines are poorly ventilated, have low current densities, and require a long time to reach the final temperature; field coils require longer than armature coils because they are stationary and the current density in the wire is very low.

**119. Permissible temperature rise.** Cotton insulation should not be operated continuously at temperatures greater than about 90 deg. cent. This permits a temperature rise of 50 deg. cent. with an air temperature of 40 deg cent.

---

**120. Intermittent ratings.** Suppose that a machine is operating on a continuous cycle, $x$ min. loaded and $y$ min. without load. The temperature of the machine will vary during each cycle between the values $\theta_x$ and $\theta_y$ (Fig. 50), where the temperature increase in the interval $x$ is equal to the temperature decrease in the interval $y$. Under these service conditions, $\theta_x$, the highest operating temperature, is less than $\theta_m$, the maximum temperature that would be obtained on continuous operation under load. For this service, therefore, a machine may be designed with higher copper and iron densities than otherwise it would have if designed for the same load but for continuous operation. It must be noted that, if the machine is stationary during the period of no load, the drop in temperature is small, and the rating of the machine cannot be made much greater than if it were operating on continuous load.

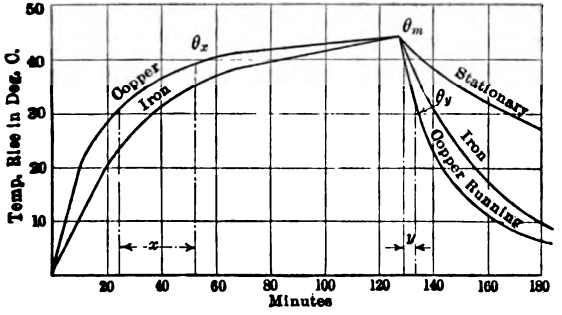

FIG. 50.—Heating and cooling curves of a direct-current motor.

**121. Heat conduction in the armature core.** The hottest part of the core is at $A$, Fig. 51; consequently the heat has to be conducted along the laminations and dissipated from surfaces $B$, and also across the laminations and layers of varnish and dissipated from surfaces $C$. The conductivity along the laminations is about fifty times that across the laminations, but the end surface of the laminations is small compared with the surface of the vent ducts, so that **radial ducts** are effective and necessary.

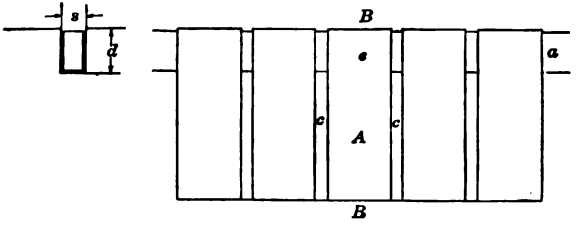

FIG. 51.—Heat conduction in armature core.

**122. Flux density and peripheral velocity.** The peripheral velocity of a machine in ft. per min. is

$$v = 10 \times \text{pole pitch in inches} \times \text{frequency in cycles per sec.}$$

Hence for a given frequency, the peripheral velocity of the machine is proportional to its pole pitch. The flux in the armature core of a direct-current machine is always alternating, and the **frequency** is equal to the product of the revolutions per sec. and the number of pairs of poles (interpoles excluded).

Digitized by Google

The core length being fixed, the longer the pole pitch the greater will be the flux per pole and the deeper the core required to carry this flux. When the peripheral velocity is high, the core is therefore deep and the vent ducts have a large surface and are very effective, so that the ventilation is good. The loss, however, is large since much iron is used in the core. When the peripheral velocity is low, the core is shallow and the vent ducts are not very effective because of their small surface, and the ventilation is poor; the loss, however, is small because there is not much iron in the core. It is found that, for a given frequency, the same flux densities can be used for all peripheral velocities.

**123. Tooth and core densities.** For frequencies up to 60 cycles per sec. and for a temperature rise of less than 50 deg. cent., the following flux densities may be used:

| | |
|---|---|
| Actual maximum tooth density | 150,000 lines per sq. in.<br>23,000 lines per sq. cm. |
| Average core density | 85,000 lines per sq. in.<br>13,000 lines per sq. cm. |

Higher densities may be used for frequencies lower than 60 cycles, as far as heating is concerned; but, with a greater density than the above, the core becomes saturated and the cost of the extra field copper required to send the flux through a saturated core is greater than the cost of the extra iron required to keep the flux density below the saturation point. There is no such objection to high tooth densities, because a machine with saturated teeth and a short air-gap is just as effective in preventing field distortion as a machine with unsaturated teeth and a long air-gap. With tooth densities greater than the above, it is difficult to predetermine the ampere-turns for the teeth with sufficient accuracy to ensure enough field margin to give normal voltage at full load, because the permeability of the iron used may be lower than was expected.

**124. Heating of armature windings.** The heating of the end connections must be considered separately from the heating of the core, because the kind of radiating surface is different, and also the manner in which it is cooled. The temperature rise is proportional to

$$\frac{\text{ampere-conductors per in. of periphery}}{\text{cir. mils per amp.}} \qquad (24)$$

and may be obtained from Fig. 52. For a given loss per unit area of radiating surface, a large machine operates at a lower temperature than a small one because its windings are not so crowded on the ends, and free passage of air into the machine is not restricted by the bearing housings.

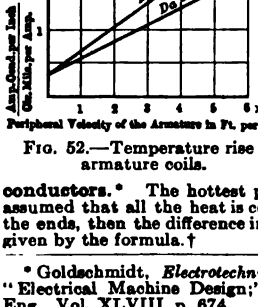

FIG. 52.—Temperature rise of armature coils.

**125. Overload temperatures.** Due to the fact that the heat loss in the copper has to pass through the insulation or be dissipated from the end connections, the maximum rise in temperature of a machine will be more nearly proportional to the copper loss than to the total loss in armature core and copper. A large number of tests on standard machines have shown that the temperature rise of an armature is approximately proportional to the sum of the armature copper loss plus 30 per cent. of the iron loss.

**126. Temperature gradient in the conductors.*** The hottest part of the winding is at *e*, Fig. 51. If it be assumed that all the heat is conducted along the copper and dissipated from the ends, then the difference in temperature between *e* and *a* in deg. cent. is given by the formula.†

$$\frac{5.7\times10^4\times(\text{length } ac \text{ in inches})^2}{(\text{cir. mils per amp.})^2} \quad \text{(deg. cent.)} \qquad (25)$$

If $ac$ is 10 in., and the number of cir. mils per amp. is 500, then this temperature difference is 23 deg. cent.

Much of the heat, however, is conducted through the insulation and, assuming that all the heat travels in this direction, the temperature difference between the copper and the surrounding iron, in deg. C., is given by the formula

$$\frac{1}{0.003}\left(\frac{\text{ampere-conductors per slot}}{\text{cir. mils per amp.}}\right)\times\left(\frac{\text{thickness of insul.}}{2d+s}\right) \qquad (26)$$

In the machine shown in Fig. 35, the design data is as follows:

| | |
|---|---|
| Ampere-conductors per in. | = 730 |
| Slot pitch | = 0.91 in. |
| Ampere-conductors per slot | = 670 |
| Cir. mils per amp. | = 560 |
| $2d+s$ | = 3.63 in., Fig. 51 |
| Thickness of insulation | = 0.06 in. including clearance |
| Temperature difference | = 6.5 deg. cent. |

**127. Commutator heating.** The direction of the air circulation in a commutator with open necks is shown in Fig. 53, and the temperature rise may be obtained from the heating curve. The radiating surface is taken as $\pi D_c F$. The effect of the necks has not yet been determined experimentally. Part of the neck from $a$ to $b$ can be closed up without affecting the ventilation or the temperature rise to any great extent. The losses are assumed to be brush friction and contact resistance losses; hence if the commutation is poor and the brushes chatter badly the temperature rise may be higher than that obtained from the curve.

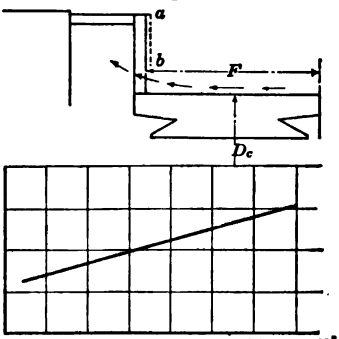

FIG. 53.—Temperature rise of commutators.

**128. Field coil heating.** The temperature rise of the coil surface is proportional to the loss per unit area of external surface and may be obtained from Fig. 44 if $B$, Fig. 42, is taken as the radiating surface. The effect of armature fanning can readily be understood; a short coil is more effective than a long one because of the larger per cent. of the loss that is dissipated from the ends of the coil. Ventilating openings, as shown in $C$, Fig. 49, allow the loss per unit area of external surface to be 50 per cent. greater than for an unventilated coil.

**129. The maximum temperature*** of the coil is that which limits the current it can carry, but this temperature cannot readily be determined experimentally. **The external surface temperature** may be measured by a thermometer and the **mean temperature** can be found by the increase in resistance of the coil. The resistance at any temperature $t$ is approximately $R_t = R_o(1+0.004t)$, where $R_o$ is the resistance at 0 deg. cent., and $t$ is expressed in deg. cent. The ratio between the maximum and the mean temperatures seldom exceeds 1.2, but the ratio between the mean and the external surface temperatures may have any value from 1.4 to 3 depending on the thickness of the coil and the amount of insulation used, an average value for coils 2 in. thick, made of double-cotton-covered wire and impregnated, is 1.5 when no external protecting covering is used.

**130. Semi-enclosed machines** have the frame openings screened with perforated sheet metal. This prevents free circulation of air through the machine and causes the temperature to rise, on an average, about 20 per cent. higher than if operating as an open machine.

**131. In totally enclosed machines,** the temperature rise of the core and the coils is proportional to the total loss in the machine (neglecting bearing friction); it is independent of the distribution of this loss and may be found from Fig. 54. The rating as an enclosed machine will be considerably lower than that as an open machine. A casing around the machine makes it equivalent to an enclosed machine with an extra large radiating surface; the casing should be of heat-conducting material such as sheet metal and should not be of wood. Fans on the armature help in the cooling of enclosed machines by blowing the hot air against the casing.

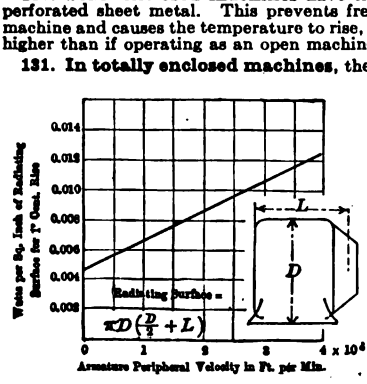

FIG. 54.—Temperature rise of enclosed motors.

**132. Forced ventilation,*** whereby air is blown through a machine by an external fan or by a fan attached to the armature, allows the machine to have the same rating as it would have when operating as an open machine; 100 cu. ft. (2.8 cu. m.) of air per kw. loss should be supplied for a temperature rise of the windings and the core of 40 deg. cent.

## EFFICIENCY AND LOSSES

**133. The iron losses†** consist of hysteresis and eddy-current losses in the armature teeth and core; these may be kept small by the use of special grades of iron (Sec. 4) and by the use of thin and well-varnished laminations. There are losses also in the end heads and spider due to leakage flux; losses due to filing of the slots which short-circuit the laminations; losses due to the fact that the core flux takes the shortest path and crowds in behind the teeth, so that the core density is not uniform; and pole-face losses‡ due to the movement of the armature teeth past the faces of the poles. In order to minimize the pole-face losses, the pole faces should be laminated if the slot opening is greater than twice the air-gap clearance.

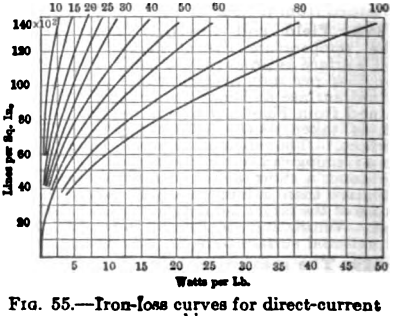

FIG. 55.—Iron-loss curves for direct-current machines.

**134. The iron losses increase with the load** if the flux per pole is kept

*Gray. "Heating of Pipe-ventilated Machines," London Electrician, Jan. 16, 1914.

†Thornton. "Distribution of Magnetic Induction in Armatures," *Journal* of Inst. of Elec. Eng., Vol. XXXVII, p. 125.

Digitized by Google

constant, because of field distortion, as the densities are then very high under alternate pole tips.

**135. The individual iron losses cannot be calculated separately,** and curves such as those in Fig. 55, obtained by tests on completed machines, must be used as follows:

Taking the machine shown in Fig. 35:

| | |
|---|---|
| Actual maximum tooth density | = 150,000 lines per sq. in. |
| Average core density | = 84,000 lines per sq. in. |
| Weight of armature teeth | = 385 lb. |
| Weight of armature core | = 2,300 lb. |
| Frequency = $p \times$ r.p.m./120 | = 16.6 cycles per sec. |
| Tooth loss per lb. | = 6 watts, from Fig. 55. |
| Core-loss per lb. | = 1.8 watts. |

Total iron loss = $(385 \times 6) + (2{,}300 \times 1.8) = 6{,}450$ watts.

**136. The armature copper loss** is given by the formula

$$\frac{ZLI_a^2}{\text{c.m.}} \qquad \text{(watts)} \qquad (27)$$

where $Z$ is the number of conductors, $L$ is the length of one conductor in in. (Fig. 56), $I_a$ is the current in each conductor, or the total current divided by the number of armature paths, and c.m. is the cross-section of each conductor in cir. mils.

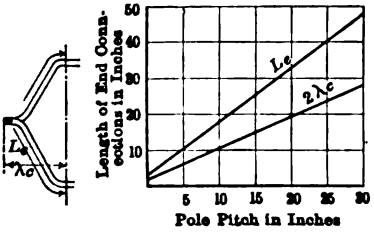

FIG. 56.—Dimensions of coils.

**137. The shunt excitation loss** equals $E_t I_f$ watts, where $E_t$ is the terminal voltage and $I_f$ the shunt current. In a generator, about 20 per cent. of this loss will be in the shunt-field rheostat.

**138. The series excitation loss** equals $I_a^2 R_s$ watts, where $I_a$ is the total current in the machine and $R_s$ is the combined parallel resistance of the series field coils and the series shunt.

**139. The brush contact resistance loss** has been discussed in Par. 38 and equals $E_b I_a$ watts, where $E_b$ is the voltage drop per pair of brushes and $I_a$ is the total current of the machine.

**140. The bearing friction loss** for moderate-speed bearings with ring lubrication and light machine oil is given by the formula

$$0.8dl\left(\frac{v}{100}\right)^{\frac{3}{2}} \qquad \text{(watts)} \qquad (28)$$

where $d$ is the bearing diameter in inches, $l$ is the bearing length in inches, and $v$ is the rubbing velocity in feet per min.

**141. The brush friction loss,** assuming the coefficient of friction to be 0.28 and the brush pressure to be 2 lb. per sq. in., is given by the formula

$$1.25\,A\frac{V}{100} \qquad \text{(watts)} \qquad (29)$$

where $A$ is the total brush rubbing surface in square inches, and $V$ is the rubbing velocity in feet per min. The brush pressure is generally less than 2 lb. per sq. in. (0.14 kg. per sq. cm.) except for railway motors, where it may be twice as large in order to keep the contact firm in spite of the vibration of the machine.

**142. The windage loss** cannot be accurately calculated and, with peripheral velocities less than 6,000 ft. per min., is so small that it may be neglected.

**143. The efficiency** of a generator is given by the expression

$$Eff_g = \frac{\text{output}}{\text{output} + \text{losses}} \qquad (30)$$

Digitized by Google

The efficiency of a motor is expressed

$$Eff_m = \frac{\text{input} - \text{losses}}{\text{input}} \qquad (31)$$

When the copper losses only are taken, the result is the **electrical efficiency.** The **commercial efficiency,** which is the important one, is obtained by substituting the total losses in the above equations.

## GENERATOR CHARACTERISTICS AND REGULATION

**144. External characteristics of separately excited generators.** Fig. 57 shows some of the saturation curves of a continuous current generator. Given a constant excitation of 18 amp., the terminal voltage at no load is 320, at full load is 292, and at twice full load is 262 volts. The relation between $E_t$, the terminal voltage, and $I_a$, the load current, is given in curve 1, Fig. 58, the excitation and the speed being constant. This curve is called the external characteristic of the machine. The voltage drops as the load increases because the cross-magnetising and the demagnetising effects of armature reaction reduce the flux per pole, while part of the generated voltage is required to send the armature current through the armature and brushes. The demagnetising ampere-turns per pole are directly proportional to the armature current, but their effect in reducing the flux increases as the flux density decreases.

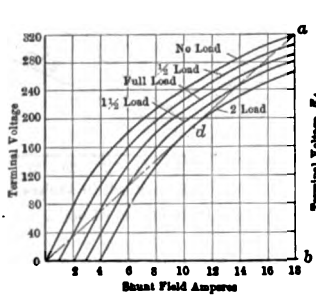

FIG. 57.—Saturation curves.

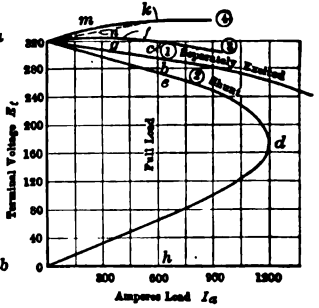

FIG. 58.—External characteristics.

**145. The external characteristic of a shunt machine** is plotted in curve 2, Fig. 58; the drop in voltage is greater than in a separately excited machine because, since the field-coil resistance is constant, the exciting current in the shunt coils decreases as $E_t$ decreases. The points for this characteristic curve are obtained as follows: the dotted straight line in Fig. 57 is drawn through the point $a$, where $ab/ob = {}^{320}/_{18} = 17.8$ ohms, the latter being the constant field resistance. With a terminal voltage of 320 and the corresponding shunt current of 18 amp., the load current is zero. With a terminal voltage of 272 and the corresponding shunt current of 15.3 amp., full-load current is required to give the proper armature reaction. As the resistance of the external circuit is reduced the armature current increases and the terminal voltage decreases until point $d$ is reached, after which a further reduction in external resistance causes such a large drop in voltage that the load current decreases. For example, with a terminal voltage of 63 and the corresponding shunt current of 3.55 amp., full-load armature current is sufficient to give the proper armature reaction.

**146. Critical resistance of shunt generators.** The external resistance equals $E_t/I_s$, and may be found from curve 2, Fig. 58. Using the value so found, the relation between terminal voltage and external resistance, and also that between current and external resistance, are plotted in Fig. 59. The critical resistance is 0.1 ohms; whenever the external resist-

Digitized by Google

ance is reduced below this value, the machine becomes completely demagnetised (except for the residual magnetism), and the terminal voltage and the armature current both become practically zero.

**147. When a shunt generator is short-circuited** the machine is demagnetised and the current becomes negligible (Fig. 59). At the instant of short-circuit, however, the flux in the pole cannot reduce suddenly to zero, and the voltage due to this flux will send a large current through the circuit; at the end of a few seconds, however, the current will have become zero.

**148. Instability of unsaturated shunt generators.** If the no-load, normal voltage point on the saturation curve is $a$, Fig. 60, below the point of saturation, then the overload capacity of the machine will be small, and the change of voltage with load will be large. Furthermore, a slight decrease in speed will cause a decrease in the generated voltage, which will decrease the shunt field current and cause the voltage to drop still further. If $ac$ is tangent to the saturation curve at point $a$, then the ratio of voltage change to the change of speed producing it, is $ab/oc$.

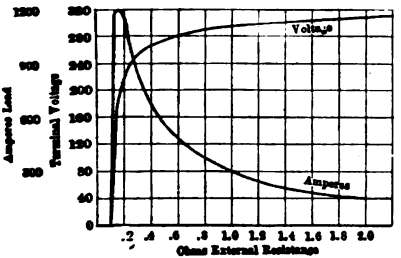

FIG. 59.—Shunt characteristics on a resistance base.

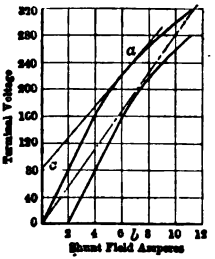

FIG. 60.—No-load and full-load saturation curves.

**149. The regulation** of electrical machinery is defined in the A. I. E. E. Standardization Rules (Sec. 24). The **voltage regulation** of a separately excited generator is $bc/bh$ (Fig. 58); for a shunt generator it is $ec/eh$ (Fig. 58); for a flat-compounded generator it is $fg/ch$; and for an overcompounded generator it is $mn/hk$ (Fig. 58). The **current regulation** of a constant-current generator depends largely on the type of regulator used and is defined as the ratio of the maximum difference of current from the rated load value (occurring within the range from rated load to short-circuit, or minimum limit of operation) to the rated load current.

**150. To maintain the terminal voltage constant,** shunt generators may be operated with an adjustable resistance in series with the shunt field coils; this resistance may be reduced automatically, or by hand, as the load increases. Automatic regulators for this purpose generally consist of a solenoid connected across the terminals of the machine, acting as a relay which will open or close an operating circuit and vary the resistance of the field circuit as required.

**151. The Tirrill Regulator,** described in Sec. 10, periodically short-circuits part of the field rheostat by means of light vibrating contacts of small inertia; the time during which the rheostat is short-circuited or is active determines the average field current and therefore the voltage of the machine.

**152. Compound machines,** operated without a regulator, keep the voltage approximately constant from no load to full load because, due to the series field coils, the total excitation increases with the load; the machine is then said to be **flat-compounded.** By the use of an extra strong series field, the voltage may be made to increase with the load; the machine is then said to be **overcompounded.** Curves 3 and 4, Fig. 58, show the

Digitized by Google

characteristic curves for compound generators. The compounding of a machine may be reduced by shunting the series field coils with a resistance; this resistance is called a "series shunt."

**153. Series generators.** Curve 1, Fig. 61, shows the relation between voltage and current if there is no armature resistance or armature reaction. This is really the no-load saturation curve of the machine and is determined by separately exciting the field coils so that no current flows in the armature. Curve 2 shows the actual relation between terminal voltage and load current.

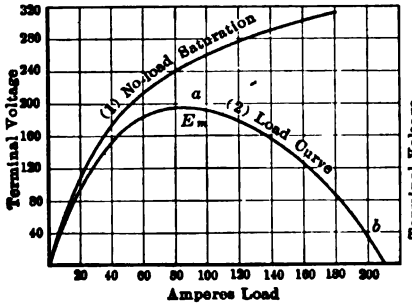

FIG. 61.

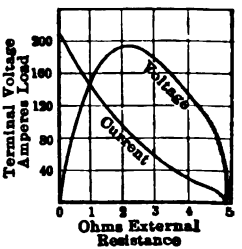

FIG. 62.

FIGS. 61 AND 62.—Characteristic curves of a series generator.

The total voltage drop consists of that portion due to the decrease in flux caused by armature reaction, and that required to send the current through the armature, brushes and series field coils.

**154. Critical resistance of series generators.** The values of current in a series generator and the resistance of the external circuit are plotted in Fig. 62. The critical resistance of the machine is 4.9 ohms; with an external resistance greater than this, the machine will not excite, or build up.

**155. Series machines** were formerly used as **constant-current generators** for the operation of **arc lamps** in series, but few of them are now in service. Specially designed machines were operated with automatic regulators so as to have the line *ab* (Fig. 61) nearly vertical, and the current practically constant for all voltages up to $E_m$ (Fig. 61).

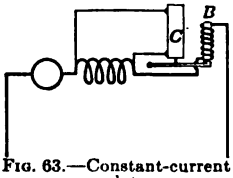

FIG. 63.—Constant-current regulator.

**156. The Brush regulator,** shown diagrammatically in Fig. 63, has been used as a **constant-current regulator.** The carbon pile *C* has the property that its resistance decreases through a wide range as the pressure between the ends increases. If the current in the external circuit increases, the pull of the solenoid *B* also increases, and the carbon pile is compressed and its resistance reduced so that it shunts more of the current from the series field coils; the flux in the machine is therefore reduced and the voltage drops until the current reaches the value for which the regulator was set. Other types of constant-current regulators are described in Par. **209** and **212.**

## MOTOR CHARACTERISTICS AND REGULATION

**157. Counter e.m.f.** It was pointed out in Par. **6** that, since a motor armature revolves in a magnetic field, an e.m.f. is generated in the conductors which is opposed to the direction of the current and is called the counter e.m.f. The applied e.m.f. must be large enough to overcome the counter

Digitized by Google

e.m.f. and also to send the armature current $I_a$ through $R_m$, the resistance of the armature winding, the brushes and the series field coils; or

$$E_a = E_b + I_a R_m \quad \text{(volts)} \tag{32}$$

where $E_a$ is the applied e.m.f. and $E_b$, the counter e.m.f., is given by Eq. 9, Par. 60.

**158. Shifting of the brushes.** It may be seen from Fig. 2 that, while the brushes of a generator are shifted forward in the direction of motion to help commutation, those of a motor have to be shifted backward. In each case, however, the armature reaction reduces the flux per pole.

**159. The torque equation.** The torque of a motor is proportional to the number of conductors on the armature, to the current per conductor and to the total flux in the machine. The formula for the torque is

$$\text{torque} = 0.1175\, Z\, \phi I_a \left(\frac{\text{poles}}{\text{paths}}\right) 10^{-8} \quad \text{(lb. at 1 ft. rad.)} \tag{33}$$

where $Z$ is the total number of armature conductors, $\phi$ is the total flux per pole, and $I_a$ is the armature current taken from the line.

**160. The speed equation** is

$$E_b = E_a - I_a R_m = Z\phi \left(\frac{\text{r.p.m.}}{60}\right) \left(\frac{\text{poles}}{\text{paths}}\right) 10^{-8} \quad \text{(volts)} \tag{34}$$

or

$$\text{r.p.m.} = 60 \left(\frac{E_a - I_a R_m}{Z\phi}\right) \left(\frac{\text{paths}}{\text{poles}}\right) 10^{8} \tag{35}$$

For a given motor the number of armature conductors $Z$, the number of poles, and the number of armature paths, are constant. The torque can therefore be expressed as

$$\text{torque} = \text{a constant} \times \phi I_a \tag{36}$$

and the speed, likewise, is expressed

$$\text{r.p.m.} = \text{a constant} \times \left(\frac{E_a - I_a R_m}{\phi}\right). \tag{37}$$

**161. Shunt-motor speed and torque.** In this case $E_a$, $R_m$ and $\phi$ are constant, and the speed and torque curves are shown in curves 1, Fig. 64; the effective torque is less than that generated, by the torque required for the windage and the bearing and brush friction. The drop in speed from no load to full load seldom exceeds 5 per cent.; indeed, since $\phi$, the flux per pole, decreases with increase of load, due to armature reaction, the speed may remain approximately constant up to full load.

**162. Effect of field-coil heating on speed.** The field-coil resistance increases and the exciting current decreases about 20 per cent. as the field coils increase in temperature. The flux per pole is therefore less and the speed greater when the machine is hot than when cold, unless a field rheostat is manipulated to keep the exciting current constant. The effect of change of exciting current on speed is minimised by having the magnetic circuit well saturated, so that a large change in current will produce only a small change in flux.

**163. Variable-speed operation of shunt motors** can best be investigated by means of Eq. 37, Par. 160. In order to increase the speed, $\phi$ must be reduced by inserting a resistance in series with the field coils. In order to decrease the speed below the value which it has with full field, the quantity $(E_a - I_a R_m)$ must be decreased by placing a resistance in series with the armature. The latter resistance must be able to carry the armature current, but the starting resistance must not be used for this purpose since it is designed for starting duty only, and would burn out if allowed to carry full-load current for more than a few minutes.

**164. Speed control of shunt motors by armature resistance** is not very satisfactory, since the speed regulation is bad. If a motor is operating with full-load current at half speed, about 50 per cent. of the applied voltage is consumed in the resistance, but if the load were decreased, so that only half of full-load current was required, then only 25 per cent. of the applied voltage would be consumed in the same external resistance, and the motor speed would increase to 75 per cent. of normal speed, unless the external

Digitized by Google

control resistance were automatically increased with decrease of load. Du to the large voltage drop across the external resistance, the efficiency of th system is low.

**165. When the speed of shunt motors is controlled by field resist ance,** the speed regulation and the efficiency are both good, but the commu tation is generally poor because, at high speeds, the main field is weaker tha normal while the armature field is unchanged, so that the field distortion i excessive and the commutating field under the pole tip consequently dis appears (Par. 35). The reactance voltage also is increased (Par. 45). Wit standard shunt motors without interpoles, it is generally impossible to in crease the speed more than 60 per cent. by field weakening without havin trouble due to sparking, the output of the machine being the normal fu load.

**166. Speed changes of shunt motors under rapidly fluctuatin loads.*** When the load on a shunt motor increases slowly, the flux per pol decreases due to armature reaction and the speed (Eq. 37, Par. 160) re mains approximately constant. If however, the load changes rapidly the flux per pole cannot chang rapidly due to the self-induction o the field coils; the machine ther operates for the instant as a con stant-flux machine, and the speed drops rapidly to allow the counte e.m.f. to decrease and the necessar current to flow.

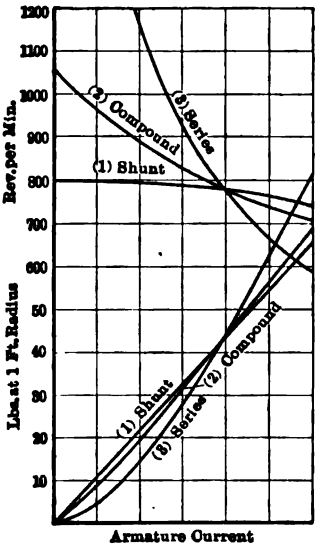

FIG. 64.—Motor characteristics.

**167. Speed and torque of series motors.** The speed equation (Eq 37, Par. 160) and the torque equa tion (Eq. 33, Par. 159) apply t motors of all continuous-curren types. In the case of series motor the flux $\phi$ increases with the arma ture current $I_a$; the torque would b proportional to $I_a^2$ were it not tha the magnetic circuit becomes satu rated with increase of current. Sinc $\phi$ increases with load, the speed drop as the load increases. The speed and torque characteristics are shown in curves 3, Fig. 64.

**168. Excessive speeds of series motors on small loads.** If th load on a series motor becomes small the speed becomes very high, so tha a series motor should always b geared or direct-connected to the load. If it were belted, and the bel broke, the motor would run awa and would probably burst.

**169. Speed adjustment of series motors.** For a given load, and there fore for a given current, the speed of a series motor can be increased by shunting the series winding or by short-circuiting some of the series turns so as to reduce the flux. The speed can be decreased by inserting resistance in series with the armature.

**170. The compound motor** is a compromise between the shunt and the series motor. Because of the series winding, which assists the shunt winding, the flux per pole increases with the load, so that the torque increases more rapidly and the speed decreases more rapidly than if the series winding was not connected, but the motor cannot run away on light loads, because of the

* Short, E. W. "Inherent Regulation of Direct-current Motor;" *Journal* of Inst. of Elec. Eng., Vol. XLVI, p. 171.

Digitized by Google

shunt excitation. The speed and torque characteristics for such a machine are shown in curves 2, Fig. 64. The speed of a compound motor can be adjusted by armature and field rheostats, just as in the shunt machine (Par. 163).

171. **Automatic speed regulation.** To keep the speed constant under all conditions of load some kind of centrifugal governor may be used to operate on the shunt-field rheostat. A piece of apparatus of this kind now on the market* is an adaptation of the Tirrill voltage regulator, in which a centrifugal control device mounted on the motor shaft performs the functions of the main control magnet in the standard regulator. The regulator periodically short-circuits part of the shunt-field rheostat by means of light vibrating contacts of small inertia. The time during which the rheostat is short-circuited, or is active, determines the average field current and the flux per pole, and therefore the speed of the machine. When the speed is too high, the centrifugal device short-circuits the rheostat for a long period and allows the flux per pole to increase and the speed to decrease.

172. **The differential motor** is a compound-wound machine with the series winding opposing the shunt winding, so that the flux will decrease as the load increases and the speed be constant from no load to full load, or actually increase with increase of load. The series winding of such a motor should be short-circuited when starting the machine, so that the starting current will not be excessive. Differential motors are rarely used, because the speed of the shunt motor is so nearly constant from no load to full load that the extra complication of the differential winding is rarely necessary. Differential windings are used to some extent for small motors, in order to secure constant speed with variable load.

173. **Unstable operation with rising-speed characteristic.** Upon suddenly increasing the load torque on a differential motor, designed for a rising-speed characteristic, the speed for a brief instant decreases. This results in a momentary drop of counter e.m.f., which admits a larger armature current, in turn weakening the resultant field strength and further reducing the counter e.m.f. The attendant increase in armature current increases the armature torque, and the reactions are such that the latter continues to increase until it exceeds the load torque and commences to accelerate the armature. The increase in speed continues until the rising counter e.m.f. finally limits the armature current to a value at which the armature torque equals the load torque, and the speed becomes constant. These reactions, with change of load, occur quite rapidly; if, however, the field cores are large and massive, changes in flux attendant upon sudden changes in m.m.f. will lag by an appreciable time interval, on account of eddy currents in the cores. The presence of an appreciable flux lag, with very rapidly changing loads, results in unstable operation; for example, when the load is suddenly increased, the speed will drop appreciably before it commences to accelerate, and when the load is suddenly removed, the speed will rise appreciably before it commences to decrease. The effect of the armature inertia will accentuate these defects in speed regulation. Such defects are not found in motors whose speed decreases with increasing load, *i.e.*, which have a drooping speed characteristic.

174. **Interpole motors** have a commutating field which increases with the current and is not affected by armature reaction (Par. 52). Motors which are subjected to excessive overloads, and adjustable-speed motors operating at high speeds with a weak main field, give little trouble due to sparking if supplied with interpoles. **Hunting**† takes place in interpole machines which have a **rising-speed characteristic.** Such a characteristic may be obtained by working with a weak main field and with a short air-gap under the main poles, so that the field distortion under load is large and the flux per pole decreases with increase of load due to the cross-magnetising effect of the armature (Par. 32).

Such a characteristic may also be obtained by making the interpoles too strong. If commutation is perfect, the current in the short-circuited coil will be zero when that coil is in the geometrical neutral-position. If, however,

* General Electric Company's Bulletin on "Automatic Voltage Regulators," 1913.

† Rosenberg, *Electrician*, Aug. 4, 1911.

Digitized by Google

the commutating field is too strong, the reversal of this current will be a
vanced, so that the true neutral will be shifted backward. The flux per po
will therefore decrease with increase of load, due to the demagnetising effe
produced, and the speed will increase with load.

Due to saturation of the interpole core, the interpole field will be too stro
at light loads, if of the proper strength at full load. Hunting is therefo
likely to occur at light loads, particularly if the main field is so weak that t
effect of the brush currents in demagnetising the machine is proportionate
large.

**175. Non-inductive shunts should not be used with interpo
windings** if the load fluctuates rapidly, because then the current, which
rapidly changing, will pass through the shunt rather than through the inte
pole coils, since the latter have considerable inductance, and the commutatio
will therefore be poor. To make the shunt take its proper share of the cu
rent under all conditions of load, it should be made inductive by winding
on an iron core, and the ratio of the shunt reactance to the interpole-co
reactance should be equal to the ratio of the shunt resistance to the interpole
coil resistance.

**176. Reversal of direction of motion.** In order to reverse a motor
it is necessary to reverse the current in the field coils, or in the armature, bu
not in both. In an interpole machine, the interpole winding must be
considered as part of the armature and not as part of the field system.

## WEIGHTS AND COSTS

**177. Weights and costs.** The cost figures given by different manufac-
turers on a large generator may vary as much as 50 per cent. One manu-
facturer may build an entirely new machine and charge part of the cost or
development to the order; another may offer a standard machine of larger
capacity, with a lower rating for the particular case; while still another
manufacturer may increase the rating of a machine of smaller capacity,
adding fans if necessary to keep the machine cool.

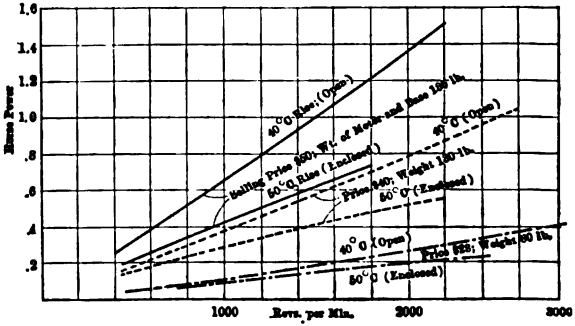

FIG. 65.—Cost of small direct-current motors without base or pulley.

**178. Varying costs of labor and material.** The cost of large units
depends largely on the cost of material, while that of small motors depends
largely on the cost of labor. These costs are continually changing, so that
it is impossible to give figures which are always reliable. The curves in
Figs. 65, 66 and 67 are average figures for standard machines.

The curves in Fig. 66 are interpreted as follows: A machine which weighs
2,000 lb. will cost $380 and will have a rating of 12 h.p. at 500 r.p.m. as an
enclosed machine on continuous duty; or 19 h.p. at 500 r.p.m. as an open
machine on continuous duty; or 31 h.p. at 500 r.p.m. with a 1-hr. rating; or
40 h.p. at 500 r.p.m. with a half-hour rating. The temperature rise on full
load is 40 deg. cent. as an open machine, and 50 deg. cent. as an enclosed
machine. The horse-power is proportional to the speed over a range of 30

per cent. above or below the rated speed. The maximum permissible speed is the highest that can be used for variable-speed operation with the particular line of machines on which data is given.

**179. Effect of voltage on weight, cost and efficiency.** If two machines are built on like frames for the same output and speed but for different voltages, the number of commutator segments will be proportional to the voltage and the commutator length will be proportional to the current. The low-voltage machine will be the heavier because of the long commutator, but, for moderate outputs, there will not be much difference in cost between a 120-volt and a 600-volt machine; the cost of the extra copper on the low-voltage machine is compensated for by the cost of the extra labor on the high-voltage commutator.

The losses will be affected in the following way: The windage, bearing friction, excitation and iron losses will be unchanged; the brush friction loss will be the smaller in the machine with the higher voltage; the contact resistance loss will be the smaller in the machine with the higher voltage because the contact drop is the same in each case and the loss is therefore proportional to the current. The armature copper loss will be unchanged if the same amount of armature copper is used in each machine, because, since the number of conductors is directly proportional to the voltage, the section of each conductor will be proportional to the current and the current density will be the same in each machine. If, however, due to the space taken by the insulation on the large number of conductors, the total amount of copper is the smaller in the machine with the higher voltage, then the copper loss will increase with the voltage and, for the same copper loss in each machine, the output of the high-voltage machine will be less than that of the low-voltage machine.

**180. Effect of speed on weight, cost and efficiency.** The output of a machine equals the product of (volts per conductor)$\times$(current per conductor)$\times$(number of conductors). For a given frame, the volts per conductor is directly proportional to the speed, and the product of (the current per conductor)$\times$(number of conductors) is constant for a constant current density and a constant weight of armature copper. The output is therefore directly proportional to the speed. As a matter of fact the flux density must decrease as the speed and the frequency increase, in order to keep down the iron loss; but the current density may increase with speed due to better ventilation. However, the output is directly proportional to the speed, over a considerable range. The higher the speed, the larger the output, and therefore the longer the commutator and the heavier the machine.

At very low speeds the number of conductors becomes large and, on account of the amount of insulation required, the total amount of copper is less than normal; the rating of such machines must therefore be reduced in faster ratio than the speed is reduced.

The total armature loss for a given frame and a given temperature rise is equal to $k(A+B\times\text{r.p.m.})$ (see Fig. 52) so that while the output is directly proportional to the speed, the losses do not increase so rapidly; and, until turbo-speeds are reached, at which the windage losses become excessive, the efficiency increases with the speed.

## STANDARD CONSTANT-POTENTIAL GENERATORS

**181. Generators for power and lighting service** are usually wound for 125 volts or 250 volts and are either flat-compounded or slightly over-compounded, so that the voltage at the lamps varies but little with change of load. The efficiency, weight, cost and speed may be obtained from Figs. 66 and 67. The regulation should be less than 2 per cent.

**182. Generators for railway service** are subject to rapidly fluctuating loads and to sudden and excessive overloads. The engine speed will drop considerably on an excessive overload unless a large flywheel is supplied, since the generator will not have the necessary flywheel effect in itself. The machines are generally wound for 550 volts at no load and 600 volts at full load, and have one terminal grounded. In order to secure proper commutation under all load conditions, interpole machines are often employed.

**183. Generators for electrolytic work** are usually low-voltage machines of large current capacity. When the terminal voltage is very low, the exciting current will be large if the machine is shunt wound, and the field rheostat

Digitized by Google

will be relatively expensive; therefore such machines are often separately excited from a source of higher voltage. For electric smelting and other work where the machine is likely to be subjected to short circuits, shunt excitation is desirable, since a shunt generator will not maintain a large current through a short circuit (Par. 147). Because of the large currents to be collected, these machines have low-resistance brushes, a high current density in the brush contact and a wide brush arc. These conditions are bad for commutation, so that interpoles are often used. Since each armature circuit has comparatively few conductors in series, and these conductors are of large section, there will be large circulating currents unless equalizers (Par. 19) of large cross-section are used. Windings such as that shown in Fig. 14 are particularly suited for generators of this type. Electrolytic generators cost and weigh more than standard 550-volt machines, because of the large amount of commutator copper required. Accurate cost figures cannot be given since the design is generally special.

184. **Boosters** are used in constant-potential systems to compensate for feeder-drop or to aid in charging storage batteries, etc. Boosters carry large currents at low voltages and have long commutators in proportion to their output. In order that the flux may be proportional to the exciting current, the magnetic circuit must not be saturated; for this reason the machine is heavier than a machine of normal voltage and of the same output. Boosters often carry large currents in a weak magnetic field, so that they must be liberally designed for commutation. **Reversible boosters** often have laminated field systems. When reversing a machine with a solid field system, eddy currents set up in the solid masses by the change of flux prevent this change from being very rapid.

185. **Exciters** are generally flat-compounded for 120 volts or 240 volts if the excited machine is operated without an automatic regulator. When operated with an automatic regulator, the exciter must be capable of supplying a voltage about 40 per cent. more than normal. The magnetic circuit should not be highly saturated, in order that the necessary increase in excitation for a given increase in voltage of the excited machine may not be too large. Machines with solid poles are quite satisfactory, as very rapid changes of voltage are not desirable. The weight, cost and efficiency of such machines may be obtained from Fig. 66.

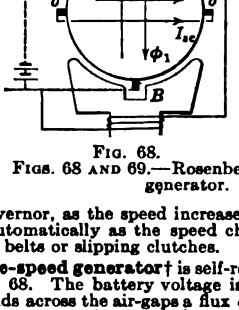

FIG. 68.

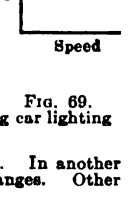

FIG. 69.

FIGS. 68 AND 69.—Rosenberg car lighting generator.

186. **Variable-speed generators*** used for the lighting of vehicles are required to give constant voltage over a wide range of speed. Many patents have been taken out on machines for this purpose. In one type the armature is moved axially out of the field by a governor, as the speed increases. In another type the brushes are shifted automatically as the speed changes. Other machines are driven by slipping belts or slipping clutches.

187. **The Rosenberg variable-speed generator**† is self-regulating and is shown diagrammatically in Fig. 68. The battery voltage is approximately constant and the shunt field sends across the air-gaps a flux $\phi_1$, which is approximately constant. The armature cuts this flux and an e.m.f. is generated between brushes *bb*, but none between brushes *BB*. The former brushes are short-circuited, so that a current flows in the armature and sets up an armature field $\phi_2$. Since the armature cuts this latter field, there is an e.m.f.

† Hall. "The Rosenberg Generator," *General Electric Review*, Vol. XIII, p. 37.

Digitized by Google

between brushes *BB* and a current *I* in the external circuit. This current *I* sets up a flux $\phi_2$, which opposes $\phi_1$, but can never exceed $\phi_1$, so that *I* cannot exceed that value at which the armature ampere-turns per pole equal the shunt-field ampere-turns per pole. The relationship between current and speed for different shunt excitations is given in Fig. 69. The direction of the current *I* is independent of the direction of rotation of the machine.

**188. A system of car lighting by a shunt generator** driven from the car axle is shown diagrammatically in Fig. 70. The diagram shows the conditions at standstill; the switch *S* is open, the generator is cut out and the battery supplies the lamps. As the car speeds up, the generator voltage increases and, when the value is reached for which solenoid *F* was set, the pull of the magnet closes the switch and connects the generator in parallel with the battery. The generator then delivers current to the battery and to the lamps, which current, flowing through coil *H*, helps to keep the switch closed. As the speed increases, the voltage of the generator and the battery current

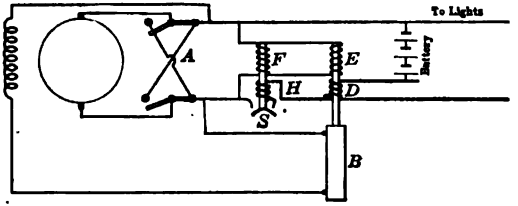

FIG. 70.—Car-lighting system.

both increase, but when full-load battery current is reached, the pull of coil *D* acts to lessen the pressure on the carbon pile *B* and the generator voltage decreases; coil *D* therefore limits the battery charging current. When the battery reaches full charge, its voltage rises to the maximum value and then the pull of coil *E* acts to lessen the pressure on the carbon pile, preventing further rise of voltage and permitting the generator to supply only the current for the lamps. When the speed drops below a certain value, the battery voltage is higher than that of the generator; current then flows back through the coil *H*, thus releasing the switch *S* and disconnecting the generator from the circuit.

Since the generator current should always be in the same direction no matter what the direction of motion of the car, a pole changer *A* is supplied; this consists of a double-throw switch operated by means of a mechanism on the shaft, which mechanism reverses the switch when the rotation of the generator reverses.

**189. The windmill generating plant** consists of a storage battery operated in parallel with a shunt generator driven by a windmill, an automatic cut-in being used to connect or disconnect the generator from the battery at the proper times. The cut-in is similar to the switch *S* in Fig. 70 and is equipped with a shunt coil connected across the generator terminals and a series coil in the line between the generator and the battery. When the windmill speed and the generator voltage are high enough to give a charging current, the shunt coil pulls up the plunger and closes the switch; the charging current then flowing in the series coil holds the switch closed. The series coil has a second plunger which is attracted downward by the charging current and, in its downward movement, opens the circuit of the shunt coil, allowing the first plunger to drop to normal position. Current cannot again flow in the shunt coil until the battery current has fallen to about 0.5 amp., when the battery switch opens, and the shunt circuit is again closed and ready to operate. See Sec. 22.

## THREE-WIRE CONSTANT-POTENTIAL GENERATORS

**190. The early three-wire systems** were operated with two similar generator units connected in series and the neutral connected to the centre

Digitized by Google

point as shown in Fig. 71. In this system the voltages $E_a$ and $E_b$ can be regulated independently of one another.

**191. The earliest type of three-wire generator** was a machine which had two armature windings on the same core, revolving in the same magnetic field, with a separate commutator for each winding. This machine was connected as shown in Fig. 72. Since the armature reaction affects each

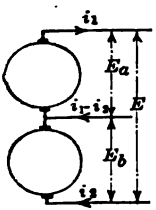

FIG. 71.

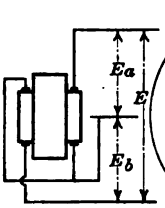

FIG. 72.

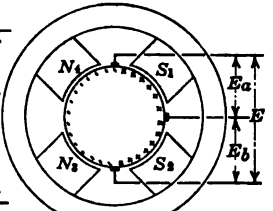

FIG. 73.

FIGS. 71, 72 AND 73.—Three-wire systems.

winding equally, it has no effect on the division of voltage, so that $E_a$ differs from $E_b$ only by the armature resistance drops in the two windings. These voltages cannot be regulated independently of one another by means of field rheostats.

**192. The Dettmar and Rothert machine** is of the **split-pole type** and is shown diagrammatically in Fig. 73 for the case of a two-pole armature revolving in a field system with four pole-pieces. Even on balanced load, the armature reaction strengthens the upper $S$ pole and weakens the lower $S$ pole, so that $E_a$ increases and $E_b$ decreases with increase of balanced load. To neutralize this effect, the weakened poles are compounded cumulatively and the strengthened poles are differentially compounded. If the shunt

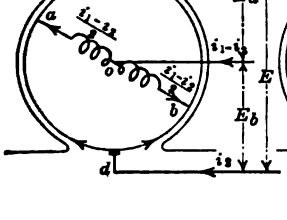

FIG. 74.

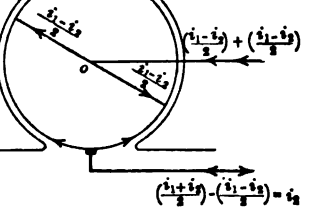

FIG. 75.

FIGS. 74 AND 75.—Unbalanced currents in three-wire generators.

coils 2 and 4 are connected across $E_a$, and the coils 1 and 3 across $E_b$, the balancing will be better than if all four coils were connected in series across $E$. The voltages $E_a$ and $E_b$ can be regulated independently, by hand, when the excitation is thus divided.

**193. The Dobrowolsky machine** is that generally used for three-wire operation. It is shown diagrammatically in Fig. 74 and consists of a standard two-wire machine with a coil of high reactance and low resistance con-

Digitized by Google

nected permanently across diametrically opposite points on the armature. The voltage between $a$ and $b$ is alternating and, even at no load, or when the load is perfectly balanced, an alternating current flows in this reactance coil. This current, however, is extremely small because the reactance is large. The center $o$ of the coil is always midway in potential between the brushes $c$ and $d$, and is connected to the neutral of the system. When the loads on the two sides of the system differ, the difference between the currents in the outside lines flows in the neutral wire and through the reactance coil, which offers only a small resistance to direct current.

**194. The current distribution in the Dobrowolsky machine*** may be considered as that due to the average current $(i_1+i_2)/2$ and a superimposed unbalanced current $(i_1-i_2)/2$, as shown in Fig. 75. The former of these currents flows in the outside lines, but does not pass through the neutral line, and so does not affect the potential of the point $o$. The unbalanced current is that which affects the voltages on the two sides of the system and this current is shown separately in Fig. 76.

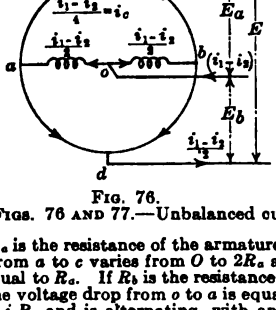

FIG. 76.

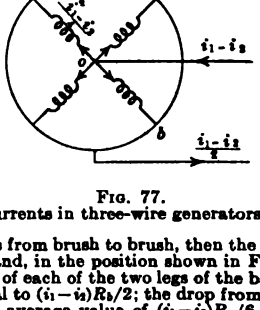

FIG. 77.

FIGS. 76 AND 77.—Unbalanced currents in three-wire generators.

If $R_a$ is the resistance of the armature from brush to brush, then the resistance from $a$ to $c$ varies from $O$ to $2R_a$ and, in the position shown in Fig. 76, it is equal to $R_a$. If $R_b$ is the resistance of each of the two legs of the balance coil, the voltage drop from $o$ to $a$ is equal to $(i_1-i_2)R_b/2$; the drop from $a$ to $c$ equals $i_aR_a$ and is alternating, with an average value of $(i_1-i_2)R_a/6$. The average drop from $o$ to $c$ is expressed by

$$\frac{(i_1-i_2)}{2}\left(\frac{R_a}{3}+R_b\right) \qquad \text{(volts)} \qquad (38)$$

**195. The unbalanced current** $(i_1-i_2)$ is generally limited to 25 per cent. of the full-load current in the outside lines and, since the armature drop at full load equals the product of full-load current and $R_a$, and seldom exceeds 3 per cent. of $E$, it follows that the average voltage from $a$ to $c$ seldom exceeds 0.25 per cent. of $E_a$ for 25 per cent. unbalanced current. Therefore the regulation of each side of the system is determined principally by the drop in the balance coil and can readily be kept within 2 per cent.

**196. The use of two balance coils** connected as shown in Fig. 77 results in a slight improvement in the machine. The average voltage drop from $o$ to $c$ in this case is

$$\frac{(i_1-i_2)}{4}\left(\frac{R_a}{3}+R_b\right) \text{ approx.} \qquad \text{(volts)} \qquad (39)$$

and is apparently less than it would be with only one coil. But when two coils are used, as in Fig. 77, each one carries half of the current carried by the single coil in Fig. 76; therefore the wire used has half the section and each of the coils in Fig. 77 has twice the resistance of the coil in Fig. 76, and the drop from $o$ to $a$ is the same in each case. The drop from $a$ to $c$ is less in Fig. 77 than in Fig. 76, but the difference is so small that it has little effect on

* Hawkins. *Journal* of Inst. of Elec. Eng., Vol. XLV, p. 704.

Digitized by Google

the regulation; it does, however, reduce the heating, because the unbalanced current has the shorter distance to travel in the armature when two balance coils are used, so that for the same armature temperature rise, the machine with the single balance coil requires slightly larger copper for the armature conductors than that with two balance coils.

**197. The rating of the balance coil.** The voltage between $a$ and $b$ (Fig. 74 to Fig. 76) is alternating and has a maximum value equal to $E$ and an effective value equal to $E/\sqrt{2}$. The current in each half of the balance coil equals $(i_1 - i_2)/2$, neglecting the small exciting current, so that the volt-ampere capacity of the balance coil equals $E(i_1 - i_2)/2\sqrt{2}$. The normal output of the generator on balanced load equals $EI$ volt-amperes, so that for 25 per cent. unbalanced current, the transformer rating in volt-amperes is only 9 per cent. of that of the generator.

**198. Compound-wound three-wire generators** have all the series coils on the $N$ poles placed on one side of the circuit and all the series coils on the $S$ poles placed on the other side of the circuit, so that the compounding is independent of the unbalancing of the load. The compounding has no effect on the voltage unbalancing.

**199. Parallel operation*** (Par. **239**) is possible if two equalisers are used, one for each set of series field coils. The diagram of connections is shown in Fig. 78; six leads per machine are required because the circuit-breakers on the switchboard must be in the armature circuit and not in the equalizer circuit.

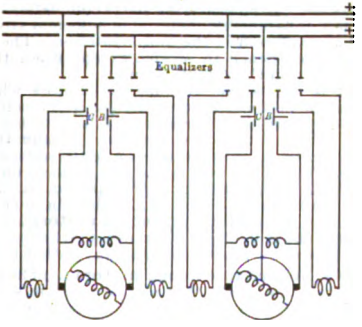

FIG. 78.—Parallel connection of three-wire generators.

## STANDARD CONSTANT-POTENTIAL MOTORS

**200. Motors for general industrial service** should be of the open type whenever possible. The totally enclosed type should not be used unless absolutely necessary. For **crane service**, a totally enclosed series motor is used with a half-hour rating. For **elevator service**, an open compound motor is used, and for **freight hoists**, an open series motor each with a 1-hr. rating.

**201. Motors for railway service** are generally wound for 550 volts. They are series wound, and so constructed that they may be easily opened for repair. The steel frame is of the split-box type, so arranged that the complete armature may be easily removed. The armature core and commutator shell are mounted on a cast-steel spider, in order that a damaged shaft may readily be removed. Railway motors have undercut mica (commutator insulation) and abrasive brushes, but the tendency is to use interpoles in order to minimise sparking and flashing-over and to allow high speeds to be obtained for suburban service by field weakening. Since the load fluctuates between wide limits, interpole shunts should not be supplied (Par. **175**).

Railway motors may be built for 1,200 volts, but the weight, size, and cost are increased for a given rating. A 100-h.p. 600-volt motor can be rebuilt to develop 75 h.p. at 1,200 volts; the larger the output the less will be the difference in rating between the high-voltage and the low-voltage machine. The 1,200-volt machine has the shorter commutator and therefore the longer core and the larger flux per pole, but has less copper in the slots due to the extra insulation required for the large number of conductors and the high voltage. A four-pole machine with an average of 20 volts between segments

* Bulletin on "I. T. E. Circuit Breakers."

Digitized by Google

will have 240 segments and, with a minimum segment and mica of 0.2 in. (0.5 cm.) thickness will have a commutator diameter of about 15 in. (38 cm.). For further information see Sec. 16.

**202. Mill motors** for rolling-mill work are built like street railway motors set on feet, and are constructed in a similar manner in order that they may be readily repaired. The shafts are made stiffer than usual, which results in greater bearing friction and smaller efficiency than in standard motors. These motors weigh and cost about 20 per cent. more than standard motors of the same rating.

**203. Mine motors** are designed to operate in a damp atmosphere and must therefore be specially impregnated with waterproof compound.

**204. Flame-proof motors,*** for operation in explosive atmospheres, must have the current-carrying parts completely enclosed in flame-tight enclosures of non-inflammable material of sufficient strength so as not to be endangered by an explosion in the motor interior. The housings of such motors should never be opened in service except when the motor is completely disconnected from the supply circuit.

It is impossible to construct motors which are **gas-tight.** When the machine becomes heated, any gas which is in the case expands and some of it is forced out along the shaft. When the motor cools again, a fresh supply of gas will be drawn into the case. **Flame-tight** motors, wherein the transmission of an inside explosion to the outside is prevented, have proved feasible. There are two types: (a) Totally enclosed machines, constructed to withstand a pressure of 110 lb. per sq. in. (7.7 kg. per sq. cm.), are built in capacities up to about 25 h.p., but become large and expensive for greater outputs. (b) **Plate-protected motors** have openings which are filled with plates about 0.02 in. (0.5 mm.) apart so as to form a labyrinth passage for the gases; the function of this labyrinth is to cool the products of combustion.

**205. Adjustable-speed motors** are efficient only when operated by field control (Par. **164**). For a wide range in speed, interpoles are required (Par. **165**). The size and cost of the machine depend on the minimum speed at which it is necessary to supply the rated output, and the maximum speed is that at which the peripheral velocity reaches a safe limit. By the use of interpoles, deep slots may be employed, and the output for a given weight increased 10 per cent. over that for a non-interpole machine, but the cost per horse-power is not reduced. The following table gives a list of ratings that may be obtained from a machine of weight $x$ (Fig. 66), suitable windings being supplied; a speed range of 3 to 1 is ample for most purposes:

46 h.p. at 800 to 1,200 rev. per min.
40 h.p. at 700 to 1,200 rev. per min.
34 h.p. at 600 to 1,200 rev. per min.
29 h.p. at 500 to 1,200 rev. per min.
20 h.p. at 350 to 1,050 rev. per min.
17 h.p. at 300 to 900 rev. per min.
14 h.p. at 250 to 750 rev. per min.
11 h.p. at 200 to 600 rev. per min.

## STANDARD CONSTANT-CURRENT GENERATORS

**206. Open-circuit windings.** Fig. 79 shows an armature with two open coils and four commutator segments. The voltage between $A$ and $B$ varies as shown in Fig. 80; the current is pulsating and only half of the armature is in use at any given instant.

**207. In the Brush arc machine** the commutator segments are made to overlap as shown diagrammatically in Fig. 81 and the brushes are wide enough to cover two overlapping segments. During the first one-eighth rev., coil $C$ alone is active and the e.m.f. in that coil passes through its maximum value. During the next one-eighth rev., coils $C$ and $D$ are in parallel; the e.m.f. in $C$ is decreasing and that in $D$ is increasing. During the next one-eighth rev., coil $C$ is cut out and coil $D$ alone is active. When two coils are in parallel the higher e.m.f. in one coil tends to reverse the current in the coil of lower

* Baum. "Fire Damp-proof Apparatus," *General Electric Review*, Vol. XIII, p. 402.

Digitized by Google

e.m.f. and, when the latter current is zero, the contact between the corresponding coil and the brush may be broken without sparking. Thus by rocking the brushes, a position of minimum sparking may be found.

**208. Ratings of Brush arc generators.** A 6,250-volt, 9.6-amp., 500-rev. per min. Brush machine weighs 9,590 lb. (4,350 kg.), occupies a floor space of 84 in. by 56 in. (2.1 by 1.4 m.) and requires 91 h.p. to drive it.

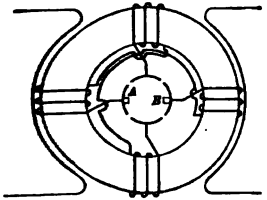

FIG. 79.—Open coil armature.

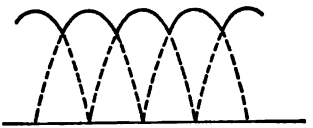

FIG. 80.—Voltage between *A B*.

**209. The Brush regulator** in its simplest form is shown in Fig. 63. A more recent type consists of two electromagnets rotated in opposite directions on a common axis by means of belts from the main shaft; between the magnets is a piece of iron which, when clutched by either electromagnet, causes the contact arm to move over the face of a rheostat which shunts the field windings. The excitation of the clutch magnets is controlled by a solenoid in the line circuit, so adjusted as to close the circuit of one magnet, or the other, according as the value of the line current is too great or too small.

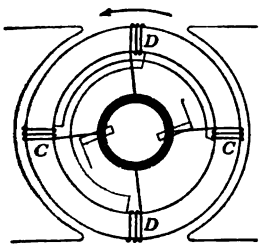

FIG. 81.—Brush type.

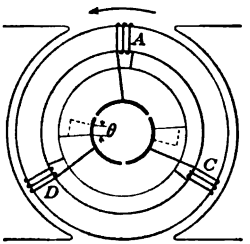

FIG. 82.—Thomson-Houston type.

Arc light generators.

**210. The Thomson-Houston machine** has three open coils spaced 120 electrical degrees apart, joined together at their inner ends, and connected to a three-part commutator at the outer ends, as shown diagrammatically in Fig. 82. At the position shown in Fig. 82, the e.m.f. in coil *C* is increasing, that in *D* is decreasing, and that in *A* is zero; coil *A* is therefore out of circuit at the instant. As the armature revolves, the e.m.f. in *A* increases and that in *D* decreases, until finally the brush disconnects the coil *D* and connects *A* in series with *C*. This cannot be done suddenly, however, or bad sparking would result; therefore the extra set of brushes (shown by dotted lines) is added and coils *A* and *D* are connected in parallel until the increasing voltage in *A* is able to reduce the current in *D* to zero, and thereupon the latter coil can be disconnected from the brush. The voltage regulation in this machine

* For tables of ratings of arc-lighting generators see Houston and Kennelly, "Recent types of Dynamo-electric Machinery," pub. 1898.

Digitized by Google

is obtained by shifting the brushes. When the brushes are in the position shown in Fig. 82, large e.m.fs. are being generated in the coils connected in series; when the brushes are shifted through 90 deg. these coils are generating low e.m.fs. and the terminal voltage is a minimum. The mechanism which shifts the brushes also varies the angle $\theta$ between brushes so as to secure good commutation with all brush positions.

**211. Rating of Thomson-Houston arc machines.*** A 2,500-volt, 10-amp., 829 rev. per min. Thomson-Houston machine weighs 5,975 lb. (2,700 kg.), occupies a floor space of 64 in. by 52 in. (1.6 × 1.3 m.) and requires 38 h.p. to drive it.

**212. The Thomson-Houston regulator** is shown diagrammatically in Fig. 83. The electromagnet $M$ is short-circuited through the contact $S$. When the line current is too strong, contact $S$ is opened by the magnet $N$ and the main current passes through $M$, which raises a lever and increases the

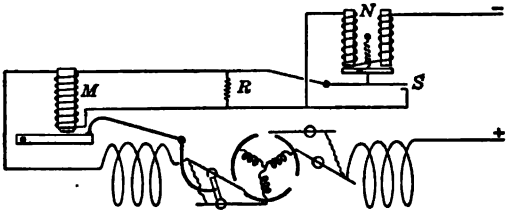

FIG. 83.—Thomson-Houston regulator.

brush arc. At the same time the brushes are shifted from the position of maximum e.m.f. The arcing at the commutator is suppressed by a mechanically-operated blower, and the arcing at the switch $S$ is minimized by the discharge resistance $R$.

**213. The Wood arc machine** has a Gramme-ring winding with a large number of commutator segments. The current is kept constant by shifting the brushes, the voltage being a maximum when the brushes are in the neutral position and zero when the brushes are under the centres of the poles. The regulator is operated by an electromagnet which lifts a lever against the pull of a spring; when the line current is too large, the magnet pulls the lever in such a manner as to engage reduction gearing with the revolving armature and cause the brushes to move to a position of lower voltage; if the current is too small, the spring pulls the lever in the opposite direction and the gearing then moves the brushes to a position of higher e.m.f.

As in the Thomson-Houston machine, the brushes of the Wood arc machine are split into two parts separated by an angle $\theta$ (Fig. 82). As the brushes move under the poles, for the purpose of reducing the terminal voltage, the e.m.f. generated in the short-circuited coils increases, and must be counterbalanced by a higher reactance voltage; this is readily obtained in a Gramme winding by reducing the brush arc so as to decrease the time of commutation. For sparkless operation, the brush angle $\theta$ should decrease as the brushes move under the poles; this is accomplished automatically by the brush-rocking device.

**214. Rating of Wood arc machines.*** A 6,250-volt, 9.6-amp., 500 rev. per min. Wood arc machine weighs 14,600 lb. (6,600 kg.), occupies a floor space of 82 in. by 80 in. (2.1 m. by 2 m.) and requires 90 h.p. to drive it.

**215. Constant-current generators for series arc lighting** are nearly obsolete, although the Rosenberg machine (Par. 167), is coming into use for the operation of searchlight arcs. Direct-current series lighting systems are now in use, but in most cases are supplied from rectifiers (Sec. 6).

## THURY SYSTEM

**216. The constant-current system** employing the types of generator described above is now rarely used, but the system has other applications, particularly in the transmission of energy over long distances (Sec. 11). Constant-current machines for operation on the **Thury System*** have been built for 5,000 volts and 150 amp. These machines have a two-circuit drum winding; a commutator with a large number of segments, so as to keep down the average potential between bars to about 20 volts; and two sets of brushes placed diametrically opposite. The claim has been made that units rated at 5,000 volts and 500 amp. can be constructed for sparkless operation, and at reasonable cost.

**217. The Thury regulator** is much like the Brush regulator (Par. **209**), except that instead of moving the contact arm of a rheostat, it shifts the brushes through 90 electrical deg. as in the Wood machine (Par. **213**). Another type of regulator has a relay in the main circuit which operates the governor on the prime mover in such a manner as to increase the speed, and therefore the voltage, if the line current becomes too small; the brushes in this case are fixed in position.

**218. Constant-current motors** must consume an e.m.f. which varies with the load. A centrifugal governor on the motor shaft causes the brushes to be shifted away from the neutral position when the speed rises due to a reduction in load, so that the counter e.m.f. is decreased, and also the total consumed e.m.f. The generator brushes are moved automatically at the same time to give this lower voltage.

**219. Sparkless operation** in all brush positions is made possible by so designing the machine that the number of armature amp.-turns per pole is equal to the exciting amp.-turns per pole. When the voltage between brushes is a maximum, the brushes are in the neutral position; but when this voltage is small, the demagnetising effect of the armature is large, and, although the brushes are under the poles, the magnetic field is small. The poles are shaped so that the short-circuited coils are always in a suitable field and therefore commutation is as good as in an interpole generator.

**220. Insulation.** Since the generators and the motors are all connected in series, the potential between a machine and the ground may be very high, although the machine itself is wound only for 5,000 volts. Hence each machine must be insulated from the ground, and driven through an insulating coupling. The power-house floor is also made of insulating material for the protection of the operators.

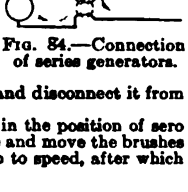

FIG. 84.—Connection of series generators.

**221. Operation of constant-current machines.** Fig. 84 shows the diagram of connections of the system. To place machine *A* in operation, it is first brought up to speed and, when full-load current flows in the local circuit, the switch *S* is thrown to the proper position to place the machine in series with the line. To take a machine out of operation, the brushes are brought slowly to the zero voltage position; then the switch *S* is manipulated to short-circuit the machine and disconnect it from the line.

To start up a motor, first see that the brushes are in the position of zero voltage, then switch the machine in series with the line and move the brushes slowly into the neutral position to bring the motor up to speed, after which the automatic regulator will keep the speed constant.

## MOTOR-GENERATOR SETS

**222. Direct-current sets** are generally used to obtain energy for special purposes from a standard lighting and power system. Thus the generator of the set will often be a special machine.

**223. The speed** of these machines is seldom fixed by external considerations and may be chosen high in order to keep down the cost. The present tendency is to use speeds such as those given in Fig. 67 for high-speed generators; machines of higher speed will be cheaper and will operate satisfactorily but will rarely be accepted by operating engineers.

* Highfield, *Journal* of Inst. of Elec. Eng., Vol. XXXVIII, p. 471; Vol. XLIX, p. 848; Still, *Electrical World*, Vol. LX, p. 1093, 1912.

Digitized by Google

**224. Standard balancer sets,*** as used for three-wire operation, consis of two like units coupled together, each wound for half of the total voltag and connected in series as shown in Fig. 85. On balanced load, they bot run "light" as motors; but with unbalanced load, the currents flow as show in Fig. 85 and machine $M$ acts as a motor and drives $G$ as a generator. Th current in $M$ is greater than that in $G$ by that amount required to suppl the armature losses. The motor speed drops with increase of load, and th generator voltage drops due to the decrease in speed and in excitation, s that $E_g$ is less than $\frac{1}{2}E$. By crossing the shunt coils, as in Fig. 86, the regula tion is improved. The motor field decreases with decrease of $E_g$ and th speed of the set increases with load; furthermore, the generator excitation being taken from $E_m$, increases with load, so that with this connection th voltages are more nearly equal under all conditions.

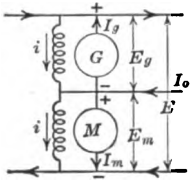

FIG. 85.

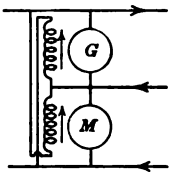

FIG. 86.

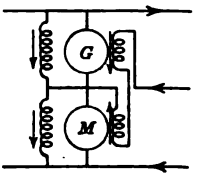

FIG. 87.

FIGS. 85, 86 AND 87.—Balancer sets.

**225. Compound balancers** are connected as in Fig. 87, so that the generator is always cumulatively compounded and the motor is compounded differentially, no matter in which direction the unbalanced current flows. This connection causes the balancer speed and the generator voltage to increase with the unbalanced load.

The generator current is expressed by the formula,

$$I_g = I_o \frac{\eta_m \times \eta_g}{1+\eta_m\eta_g} \tag{40}$$

and the motor current by

$$I_m = I_o \frac{1}{1+\eta_m\eta_g} \tag{41}$$

The efficiency in each case being given with the shunt-excitation loss neglected. The actual combined efficiency of the set is

$$\text{Eff.} = \frac{I_g}{I_m+2i} \tag{42}$$

## HOMOPOLAR MACHINES

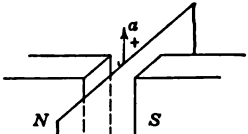

FIG. 88.—Faraday's demonstration.

**226. Theory of Operation.†** Faraday showed that, if the metal strip $A$, Fig. 88, be moved so as to cut lines of force, an e.m.f. will be established between the brushes $a$ and $b$ and a continuous current sent round the external circuit connecting them.

**227. The radial type,** shown in Fig. 89, consists of a metallic disc, rotating between poles which are excited by field coils wound concentric with the shaft. The brushes are placed at $a$ and $b$, and holes are cast in the yoke to allow access to the brushes. In Fig. 90, there are two discs mounted on the same shaft so that they are electrically connected

* Budd Frankenfield, *Electrical World*, Dec. 23, 1905; Lanier, *Electrical Journal*, Vol. IX, p. 1036.

† Gray. "Impossible Homopolar Machines," *Canadian Elec. News*, Mar. 15, 1913.

Digitized by Google

at the hub, and the total e.m.f. is twice that of one disc. Steel has been suggested for the disc material so as to reduce the reluctance of the magnetic circuit; this, however, would introduce a magnetic pull, due to inequalities in the air-gaps on the two sides of the disc, and this pull could be eliminated only by carefully adjusting the discs and then securing them in such a way as to prevent end play.

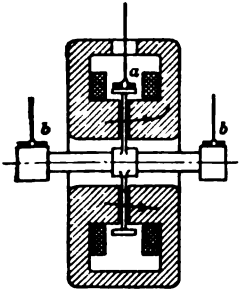

Fig. 89.

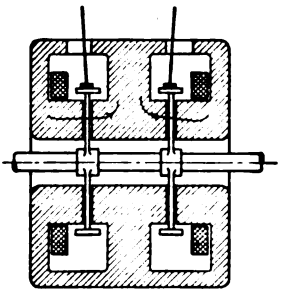

Fig. 90.

Figs. 89 and 90.—Radial type of homopolar machine.

**228. The axial type,** shown in Fig. 91, consists of a metallic cylinder rotating in a uniform magnetic field. The voltage of such a machine is low; a 300-kw., 500-volt, 3,000-rev. per min. machine with an armature diameter of 19.3 in. (49 cm.), effective core length of 12.2 in. (31 cm.) and a peripheral velocity of 15,200 ft. per min. (77 m. per sec.) generates 41.5 volts per conductor in a field of 112,000 lines per sq. in. (17,300 per sq. cm.) density. In this case twelve conductors in series are required for 500 volts, and each conductor requires two slip-rings, with brushes on each ring adequate to carry the full-load current, the rubbing velocity being about 15,000 ft. per min. (77 m.p.s.).*

**229. The brush friction loss** is very large and the total contact drop of twenty-four contacts in series is also large. The efficiency is about 88 per cent. at half load and 91 per cent. at full load.

**230. The output equation (Par. 89) for a homopolar machine** is

$$D_a^2 L_c = \left(\frac{\text{watts}}{\text{r.p.m.}}\right)\left(\frac{60.8\times 10^7}{\mathfrak{B}_g\ q}\right)\text{(cu. in.)} \quad (43)$$

where $\mathfrak{B}_g$ in the above 300-kw. machine is 112,000 lines per sq. in. and is limited by saturation; $q$ in the above machine equals $12\times 600/\pi\times 19.3 = 120$ ampere-conductors per in., a value which cannot be increased without increasing the number of brushes, and which cannot reach the value given in Fig. 29 unless some brush is devised which will collect about 1,200 amp. per sq. in. (186 amp. per sq. cm.) of contact surface.

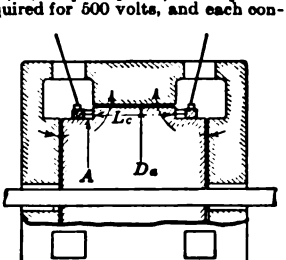

Fig. 91.—Axial type of homopolar machine.

Substituting the above values for $\mathfrak{B}_g$ and $q$ the following equation is obtained.

$$D_a^2 L_c = .45\left(\frac{\text{watts}}{\text{r.p.m.}}\right) \quad \text{(cu. in.)} \quad (44)$$

* Noeggerath. *Trans.* A. I. E. E., Vol. XXIV, p. 1.

Digitized by Google

Now the flux density in section *A*, Fig. 91, is limited to about 130,000 lines per sq. in. (20,000 per sq. cm.) so that $D_a = 1.7\,L_c$ approximately, and therefore $D_a^2 = 76$ watts/rev. per min., with the above limitations.

**231. Weight and cost.*** Because of the low value of ampere-conductors per in., made necessary by the brush rigging, the value of $D_a^2 L_c$ for a homopolar machine will generally be greater than for a machine of the standard type and the machine will be much heavier and more expensive. Therefore, until suitable brushes are found, this type of machine is not likely to be widely used except in the case of machines for low voltages and large currents.

**232. The maximum output** that can be obtained for a given number of revolutions per minute may be found by assuming a limiting peripheral velocity of 15,000 ft. per min. (77 m. per sec.). Then the output in watts is equal to $D_a^2 \times$ r.p.m./76 and

$$\text{kw} = 0.72\,\frac{(\text{perip. vel.})^2}{\text{r.p.m.}^2} \times \frac{1}{1000} = 2.5 \times 10^9/(\text{r.p.m.})^2 \qquad (45)$$

The maximum output and the speed are plotted in curve 4, Fig. 32. The points shown on the curve give the ratings of two machines now in operation.

**233. Compound-wound homopolar machines.** The idea underlying the compounding is explained by the diagram in Fig. 92, which relates to a machine having six conductors. The brushes *E* are connected to the stationary conductors *H* by means of connection pieces *G*. Only a portion of the whole length of *G* is actually employed to carry current, and the amount of this active portion can be varied by the brush rocker *F*. In practice it is sufficient to have a flexible lead instead of the fixed conductor *G*.

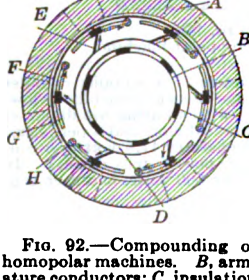

FIG. 92.—Compounding of homopolar machines. *B*, armature conductors; *C*, insulation between conductors; *D*, slip rings.

**234. Homopolar machines may be made self-exciting** and Noeggerath points out that homopolar machines may even be operated without the use of a field coil.

**235. Standard lines of homopolar machines** are not on the market; the machines are heavy and expensive if the ampere-conductors per in. are kept low so as to have a reasonably satisfactory brush rigging (Par. **230**), and are troublesome in operation unless they are excessively large. The troubles encountered in the construction and operation of a homopolar machine are described by Lamme† in connection with a 2,000-kw., 260-volt, 7,700-amp., 1,200-rev. per min. machine which had 16 slip-rings operating at a peripheral velocity of 13,200 ft. per min. (67 m. per sec.) and copper leaf brushes set against the direction of rotation, the rings being lubricated with graphite.

## OPERATION OF GENERATORS AND MOTORS

**236. Shunt-wound generators in parallel.** *A* and *B*, Fig. 93, are two similar generators feeding the same bus bars *C* and *D*. If machine *A* tends to take more than its proper share of the total load, the voltage of *A* falls, and the load is automatically thrown on *B*, the machine with the higher voltage. Furthermore, if the engine connected to *B* fails for an instant, that machine slows down, its generated e.m.f. falls, and current flows back from the line to operate it as a motor. Since the excitation remains unchanged, the machine will run at normal speed and in the same direction as before, and, as soon as the engine recovers, will again take its share of the load.

**237. Division of load between shunt generators in parallel.** The external characteristics of the two machines are shown in Fig. 95. At

* Pohl. "The Development of Tubo-generators," *Journal* of Inst. of Elec. Eng., Vol. XL, p. 239.

† Lamme. *Trans.* of A. I. E. E., Vol. **XXXI, p. 975.**

Digitized by Google

voltage $E$, the currents in the machines are $I_a$ and $I_b$, and the line current is $I_a + I_b$. To make machine $A$ take more of the load, its excitation must be increased, in order to raise its characteristic curve. If a 100-kw. machine and a 500-kw. machine have the same regulation, and therefore the same drop in voltage from no load to full load, then, as shown in Fig. 96, the machines will divide the load according to their respective capacities.

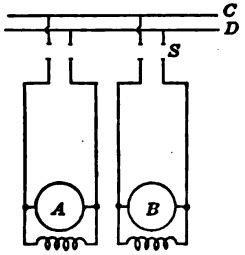

FIG. 93.—Shunt.

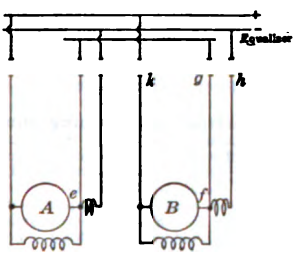

FIG. 94.—Compound.

Connections for parallel operation.

**238. Compound-wound generators in parallel.** $A$ and $B$, Fig. 94, are two compound-wound machines. If machine $A$ tends to take more than its proper share of the load the series excitation of $A$ increases, its voltage rises and it takes still more of the load, so that the operation is unstable. Furthermore, if the engine on $B$ fails for an instant, that machine slows down, its generated voltage falls and current flows back from the line to operate it as a motor. Under these conditions the shunt excitation remains unchanged, but the current in the series coils is reversed, so that, running as a motor in a weak field, the machine will tend to increase in speed and possibly run away.

**239. Equalizer bus.** To prevent instability when compound-wound machines are operated in parallel, a bus bar of large section and negligible resistance, called an equalizer bus, is connected from $e$ to $f$ as in Fig. 94. Points $e$ and $f$ are then practically at the same potential; therefore the current in each series coil is inversely proportional to the resistance of that coil, is independent of the armature current, and is always in the same direction. The machine ammeter, which indicates (at the switchboard) the current output, should always be connected in series with the lead $k$, Fig. 94. In **interpole machines**, the interpole winding is considered as part of the armature.

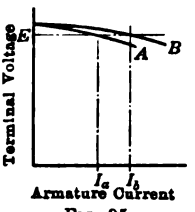

FIG. 95.

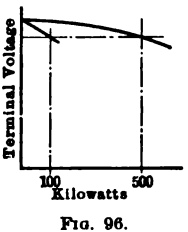

FIG. 96.

FIGS. 95 AND 96.—Division of load between two shunt generators in parallel.

**240. Series shunt.** When a single compound generator has too much compounding, a shunt in parallel with the series field coils will reduce the current in these coils and so reduce the compounding. When compound machines are operating in parallel, using an equalizer bus, the current in the series field coils depends only on the resistance of these coils; and a series shunt connected to one machine does not reduce the compounding of that machine alone, but also that of all the other machines with which it is operating in parallel. In order to reduce the compounding of a single machine, a resistance must be placed in *series*, and not in parallel with the series field

Digitized by Google

coils. A combination of series and shunt resistances can also be employed. This adjustment is made after erection. If one machine is found to take more than its share of the load, then its compounding must be reduced by means of a resistance placed in series with its series field coils.

**241. Starting and stopping a single shunt-wound generator.** It is generally safest to start with the machine entirely disconnected from the external circuit and with the field rheostat all in circuit. Then bring the generator up to speed and cut out the field resistance until the voltage of the generator is normal. The main line switch may then be closed and further adjustment of voltage made if necessary.

To stop the machine, open the feeder switches, insert all the resistance in the field-coil circuit, then open the main switch and shut down the engine.

**242. Starting and stopping shunt-wound generators in parallel.** Assume that machine *A*, Fig. 93, is running; it is required to throw machine *B* in parallel with it. This latter machine must on no account be connected to the line while coming up to speed, otherwise it will form a short circuit across the machine which is already in operation. To place machine *B* in operation, bring it up to speed with the switch *S* open, adjust the shunt rheostat until $E_b = E_a$, then close switch *S* and increase the excitation of *B* until it takes its share of the load. To disconnect this machine, its excitation should be reduced until machine *A* carries the entire load; the switch *S* may then be opened. When shunt machines are being connected in parallel for the first time, the polarity of the switches should be carefully tested with a voltmeter or its equivalent.

**243. Starting and stopping compound-wound generators.** A single machine is started and stopped in the same way as a shunt machine (Par. **241**). To place machine *B*, Fig. 94, in parallel with machine *A*, which is already running, bring the machine up to speed and excite it to give normal voltage; first close switches *g* and *h* in order to excite the series coils, then make $E_b$ equal to the bus-bar voltage and close switch *k*; the machine may then be made to take its share of the load by increasing the shunt excitation. To disconnect the machine, reduce its load to zero as in the shunt generator, and open the three switches in the reverse order.

Three separate switches are necessary for large machines, because of the large currents. For smaller machines, one double-pole switch for *g* and *h*, and a single-pole switch *k*, are sometimes used. For small machines, a three-pole switch is often used, but then the main switch is closed before the series field has its proper value and there is a momentary disturbance.

**244. Starting and stopping motors.** All except small motors, rated at a small fraction of a horse power, should be provided with a **starting box** or **starting rheostat.** Such starters, on constant-potential systems, consist in general of graded resistance connected in series with the armature, and eliminated step by step as the motor comes up to speed. The starting torque, as well as the running torque, is given by Eq. 36, Par. **159**; therefore in order to keep the starting current as small as possible, the magnetic flux should be as large as possible and the field coils should be fully energized before the armature receives any current. The counter e.m.f. at standstill is zero, and therefore the series starting resistance is necessary to limit the starting current to a safe value. Starters should be equipped with an **automatic release** which will operate under the conditions of no terminal voltage, or no current in the shunt field coils, so that the motor will not be burnt out when the terminal voltage is re-established or when the field circuit accidentally opens. For further information on starters see Sec. 5, and for information on motor control see Sec. 15.

Shunt motors may be stopped by merely opening the line switch; such motors should not be stopped by returning the handle of the starting box to the "off" position, because this method requires the opening of the field circuit while energized and gives rise to a momentary but very severe induced e.m.f. The handle of the starting-box should automatically return to the "off" position before the motor finally comes to a dead standstill.

**245. Field discharge.** If the field circuit be suddenly opened while carrying current, then, due to the rapid decrease of flux through the large

Digitized by Google

number of field-coil turns, a large e.m.f. will be induced between the two open ends. This may be sufficient to break down the insulation between the field coils and the poles. To prevent this, when a motor is disconnected from a line, the field coils should be short-circuited through the armature winding at the instant the line circuit is opened, the necessary connections being made by the starter.

**246. Installation of motors and generators.** The machine should, if possible, be placed in a cool ventilated position which is free from dirt, dust, or moisture. Machines required to operate in damp places should have the coils specially treated. The foundation should be solid to prevent vibration. If the machine is belted, the belt tension should not be too great, the distance between belt centres too short, or the pulley too small; the pulley should not have a diameter less than that recommended by the manufacturer. The belt should be flexible and without lumpy joints and the bottom side should be the tight side. After erection, clean the bearings by pouring in gasoline, drain this off through the drain cocks and then fill the bearings with light mineral oil. Before starting, see that there are no loose parts and that the brushes are making firm contact.

**247. Starting generators for the first time.** Bring the generator slowly up to speed with the field circuit open and see that the oil rings operate properly; then close the shunt field switch and bring the voltage up to normal. Run the machine without load for an hour, after which the load may gradually be increased. Generators should be thoroughly dried out in every instance before they are placed in commission.

**248. Starting motors for the first time.** Check the connections to make sure that they are correct and secure. See that the controller handle is in the starting position, then close the line switch. If the motor does not start on the first or second notch of the controller, open the line switch and look for the trouble. When starting, bring the controller handle over slowly to the running position, allowing the motor to gather speed, but do not run on the starting notches for any length of time. Run the motor without the belt for half an hour (this cannot be done with a series motor) and then put on the load. When shutting down, open the line switch and see that the controller handle returns to the starting position before the motor finally stops.

**249. Operating instructions.** Keep oil away from the commutator, brushes and windings. Do not allow dirt or dust to accumulate in or around the machine. Do not lubricate the commutator with oil; a piece of muslin moistened with vaseline may be used to clean the commutator. Emery is a conductor and should not be used in fitting brushes or cleaning the commutator; use sandpaper and do not use it on the commutator too frequently. Do not use greater brush tension than necessary; tension greater than 2 lb. per sq. in. (0.14 kg. per sq. cm.) is seldom required. When replacing brushes, use the quality and size originally supplied with the machine, and fit them to the commutator with sandpaper before use; a strip of sandpaper should be placed on the commutator below the brushes, sand side up, and pulled through in the direction of motion of the commutator. Do not open generator-field circuits quickly (Par. 113); open the switch slowly, permitting the arc to extinguish gradually, which should take about 5 sec. On large generators use a field discharge resistance, which is connected across the terminals as soon as the field switch opens; see Fig. 97.

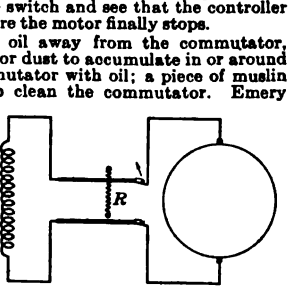

FIG. 97.—Field discharge resistance.

Do not stop quickly on account of a hot bearing, but slow down the machine and apply good clean oil. A quick shut-down will cause the bearing to "freeze." Inspect and clean the machine periodically.

**250. Poor commutation** is generally due to one or more of the following causes:

(a) Brushes not in the proper position.

(b) Bad spacing of the brush sets. This may be checked by counting the number of commutator segments between adjacent brush sets.

Digitized by Google

(c) Projecting mica. This cause may be removed by cutting out the mica between segments for $\frac{1}{16}$ in. (0.16 cm.) below the commutator surface.

(d) Rough commutator, generally caused by sudden rushes of current. When such current rushes are inherent under the operating conditions, and interpoles are not employed, it may be advisable to use abrasive brushes to keep the commutator free from rough spots.

(e) Flat bars, produced because some of the commutator segments are softer than others.

(f) High bars, generally due to soft spots in the mica clamping cones.

(g) Grooved commutator, may be prevented by staggering the brush sets so that the space between two brushes of one set is covered by a brush of the next set and the commutator wears down evenly.

(h) Poor brush contact, due to imperfect bedding of the brushes, to dirt, or to burning of the contact.

(i) Worn brushes being replaced by others of the wrong quality or size.

(j) Sticky brushes, which do not move freely in box holders and so do not follow irregularities of the commutator.

(k) Vibration due to want of balance in the armature, to poor foundations, or to a badly laced belt.

(l) Chattering of the brushes, which can generally be cured temporarily by cleaning the commutator with a piece of muslin moistened with vaseline, and may be cured permanently by changing the brush angle.

**251. Armature winding troubles** are generally due to the following causes:

(a) A broken coil, generally at the commutator end, caused by the wire connected to the commutator being too tight, excessive vibration, poor soldering at the commutator neck, or the use of copper which was not properly annealed. This trouble causes a bad arc at the instant the brush breaks contact with the segment connected to the broken coil. The trouble can be fixed temporarily by short-circuiting the commutator segments connected to the damaged coil, thereby cutting it out, care being taken not to short-circuit the coil itself.

(b) A short-circuited armature coil may be due to damaged insulation between turns or to an accumulation of copper dust in the commutator necks. A large local current will flow in this coil and cause it to become hot and to smoke.

(c) An armature coil may be reversed during repairs. The e.m.f. of the reversed coil opposes that of the other coils so that one circuit in the armature will generate less than normal voltage (Par. 19). At the moment of commutation, the conductors of this coil will be under the wrong pole tips and local sparking will take place.

**252. Field-coil troubles** are generally due to the following causes:

(a) An open circuit: If the motor is series wound, the machine will stop and cannot be started again; if a shunt motor, the machine will speed up as the flux decreases (Par. 163) and the line current will increase as the back e.m.f. diminishes, until the circuit-breakers open. If the machine is a shunt or compound generator, the generated e.m.f. will greatly decrease and a large current will flow into the machine from other generators which are operating in parallel with it, and open the circuit-breakers.

(b) A short circuit will reduce the field-coil resistance and in the case of a shunt machine, will cause the exciting current to increase and the temperature to rise. The m.m.f. of the damaged coil will be reduced and that of the other coils increased, so that the strengths of the poles will be different (Par. 19). The average flux per pole will be unchanged in a shunt machine, but will be reduced in a series machine.

(c) Reversed field coils will cause adjacent poles to have the same polarity. The polarity can be tested with a compass or, if that is not available, with a piece of soft iron which will lie along the lines of force and therefore bridge the poles if the polarity is correct, but will tend to lie axially in the direction of the shaft if the polarity is wrong.

**253. The effect of wear in the bearings** is to throw the armature out of centre with respect to the pole-pieces and cause an unbalanced pull (Par. 19).

**254. End thrust** causes heating of the bearings and is generally due to projection of the armature core beyond the magnetic field (Par. 95). End thrust may also be due to the fact that the shaft is not horizontal.

Digitized by Google

**258. Residual magnetism of the generator fields** may be "killed" by a short circuit. When this happens, the field coils must be excited from an external source, using batteries if nothing else is available.

**256. Humming** may be cured by chamfering the pole tips.

## TESTING

**257. Purpose of testing. Commercial tests** are made on standard machines to make sure that they have been properly constructed. **Acceptance tests** are made on important machines to make sure that they meet the guarantees. **Special tests** are made by the designer to find the limits of a new machine and to obtain constants and data to be used on future designs.

**258. No-load saturation, friction and iron-loss tests.** To make this test the machine is separately excited, connected as shown in Fig. 98, and driven as a generator at the rated speed by a shunt motor $M$ of such size that the rated output of the motor is approximately equal to the largest loss to be measured. The losses in the driving motor should have been previously determined and should be known for all inputs. The generator is excited to

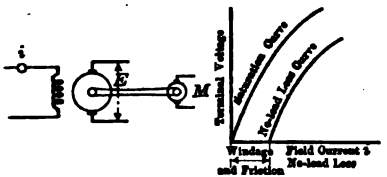

FIG. 98.—Connections for large machine.

FIG. 99.—No-load curves.

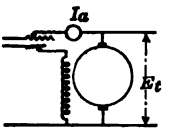

FIG. 100.—Connections for small machine.

No-load saturation, friction and iron-loss tests.

give about one and one-half times normal voltage; the excitation is then gradually reduced, the speed being kept constant, and simultaneous readings are taken of generator voltage, speed and exciting current, also of motor input, speed and excitation. The losses in the motor for a definite voltage, current, speed and excitation are known; the output can therefore be found and is equal to the sum of the iron, windage and friction losses in the generator, an allowance being made for the loss in the belt. The results are plotted as in Fig. 99. The loss with zero excitation is the windage and friction loss, from which the windage and bearing friction can be separated by taking a reading with the brushes lifted.

**259. The brush loss** varies greatly with the condition of the contact surface and a note should be made on the test sheet as to whether the test was made before or after the heat run and whether or not the commutator was cleaned and lubricated before the test was made.

**260. The saturation and no-load loss test for a small motor** is generally made by separately exciting the machine, connecting it as shown in Fig. 100, and running it idle at normal speed. The armature voltage is varied with a rheostat in the armature circuit and the excitation is adjusted to keep the speed constant. This excitation will be approximately the same as the no-load excitation as a generator, since, at no load, the applied voltage is practically equal to the back e.m.f. (Par. 157). The armature input will be the sum of the windage, friction and iron-losses and also the small copper-loss due to the no-load armature current; the latter loss can be calculated and deducted.

**261. Armature resistance.** This is generally measured by passing a known current through the stationary armature and measuring the voltage drop between the brushes and also across the terminals of the machine. This latter value is not the true voltage drop between the terminals, since the contact resistance when the machine is running is different from that when the machine is stationary.

The armature resistance is sometimes determined by passing a current through the armature and also through a standard resistance of approxi-

Digitized by Google

mately the same value and at least the same current-carrying capacity, and comparing the drops of potential across each, in which case the current need not be measured.

**262. The field-coil resistance** is determined by passing a known current through the coils and measuring the drop of potential across the field terminals.

**263. Load tests** on machines of considerable size must be made by some method whereby the power developed by the machine is not dissipated, but is made available for the test; otherwise the power-house capacity may not be large enough to test many machines and the cost of the test will be excessive.

**264. Blondel's loading-back method.** Two identical machines are required for this test. They are separately excited, connected together mechanically to run at the same speed, and their armatures are connected electrically in opposition as in Fig. 101 so that, when equally excited, there is no current in the armature circuit. An auxiliary motor $M$ is belted to the set

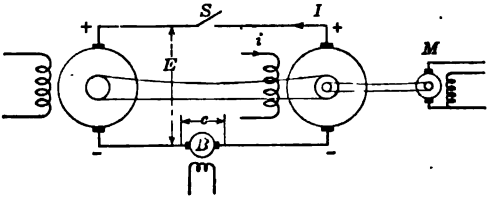

FIG. 101.—Blondel method.

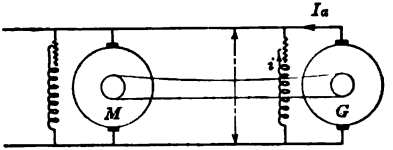

FIG. 102.—Kapp method.
Loading back tests.

and should have a capacity large enough to supply the no-load losses of both machines. The booster $B$ must carry full-load current and is used to circulate the current through the armatures of both machines. The set is brought up to speed by the auxiliary motor, the switch $S$ being open. The fields are then excited until the voltage $E$ is normal and the voltage across the switch $S$ is zero. This switch may then be closed and, by suitably exciting the booster, any desired armature current may be made to circulate. The booster supplies the copper-loss and the motor $M$ supplies the other armature losses of both machines so that $EI$ is the generator output; one-half the output of $M$ is equal to the sum of the windage, friction and iron-losses of one machine; one-half of $eI$ is the copper-loss of one machine; and $Ei$ equals the excitation loss of one machine, from all of which the efficiency may be found.

**265. The regulation** of a generator, or of a motor, may be determined from Blondel's test. The machines in this case need not be identical, but they must be of the same voltage, and the output of the testing machine must not be less than that of the machine to be tested. In the test for generator regulation, start with normal voltage $E$ and no circulating current; then excite the booster to give the desired current $I_a$ and measure $E_t$, the terminal voltage. Plot $E_t$ and $I_a$ as in Fig. 58. In the test for motor-speed regulation, keep the voltage across the motor terminals constant

by means of the booster, and vary the speed of the auxiliary motor $M$ until the circulating current has the value desired. Plot the speed and $I_a$ as in Fig. 64.

**266. Hopkinson's test.** This test is similar to Blondel's, but the booster is eliminated and the auxiliary motor is used to supply all the losses, the current in the armatures being circulated by weakening the field of one machine and strengthening that of the other. The iron-losses in the two machines are different because the fields have different excitations, so that, while the method is satisfactory for regulation and heating, it is not satisfactory for efficiency.

**267. Kapp's method** is preferred to Hopkinson's and is the one generally adopted in commercial work for regulation and heating tests; the efficiency of a machine is generally calculated from the losses. The diagram of connections is shown in Fig. 102. The losses are supplied from the testing circuit and are easily measured, but, since the copper-losses in the two machines are different, as also are the iron-losses, the method should not be used for an accurate determination of efficiency.

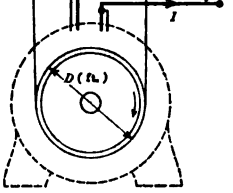

FIG. 103.—Prony-brake test.

**268. Load tests on series motors.** When a large number of **railway motors** have to be tested the loading-back method of test is used. Two motors are connected together as shown in Fig. 101 and are geared to the same countershaft so as to run at the same speed. This countershaft, driven by an auxiliary motor supplies the mechanical losses. The field coils are connected in the armature circuit and a booster is also placed in this circuit to supply the copper losses.*

**269. Prony brake test.** The efficiency is seldom determined by direct measurement of input and output except in the case of small motors which are connected directly to the line and the load then measured by means of a water-cooled **prony brake** as in Fig. 103.

$$\text{Eff.} = \frac{746\pi\, D\ (\text{r.p.m.})(T_1 - T_2)}{33{,}000\ EI} \qquad (46)$$

**270. In constant-current arc generators,** the load losses are generally large, and the efficiency of such machines is obtained by measuring the output electrically, and the input by means of a driving motor whose efficiency is known.

**271. Load saturation test.** The generator is driven by a motor of the same voltage and of larger output, and the machines are connected to the testing circuit as in Fig. 102. Starting at about 20 per cent. above normal voltage and with full-load circulating current, the excitations of the two machines are gradually reduced and a series of readings of $E_1$ and $i$ are taken, $I_a$ being constant. The results are plotted as in curve 2, Fig. 19.

**272. Heat run.** The machine is connected as in Fig. 102 and operated at rated speed and voltage, with the desired circulating current. The suggestions contained in the A. I. E. E. standardisation rules, Sec. 24, regarding measurement of temperature and conditions of test, should be followed.

**273. Insulation resistance** may be measured with a megger (Sec. 3) or by means of a high-resistance voltmeter connected as in Fig. 104. In the latter case the insulation resistance equals the resistance of the voltmeter multiplied by the ratio $(E-e)/e$, where $E$, the voltage of the testing circuit, should be the same as the normal voltage of the machine being

* For modifications of this test see:

Fay, C. J. "Testing Large Motors," *Electric Journal*, Vol. III, p. 525.

Digitized by Google

tested, and $e$ is the voltmeter reading or the drop in voltage across the voltmeter resistance.

**274. Puncture test.** To test the insulation, a high voltage is applied between the armature winding and the frame, between the field windings and the frame, and also between the shunt and the series field coils with the shunt winding disconnected from the armature. The test voltage is obtained from a small testing transformer of adjustable ratio and should be raised to the desired value smoothly and without sudden large increments; the maximum should be applied for 1 min. unless otherwise specified, and then gradually decreased. The recommendations given in Sec. 24, should be followed.

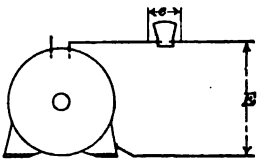

FIG. 104.—Measurement of insulation resistance.

**275. Acceptance tests.** A compound generator to be tested for efficiency, regulation, temperature, commutation and insulation would be handled as follows:

(a) Grind the brushes in place with sandpaper.

(b) Measure the armature and the field coil resistances.

(c) Place full load on the machine (Par. **272**). Adjust the brush position so that the machine is sparkless over the desired range of operation. The brushes should not be set further forward than necessary, otherwise the armature reaction will be greater than it need be. Adjust the current in the series coils with a temporary shunt to give the required voltage at no load and at full load.

(d) Keep the machine on full load until the temperatures, as indicated by the field coil resistance, have become approximately stationary; then shut down and take temperatures.

(e) Measure the armature and the field coil resistances before the machine has time to cool.

(f) Give the machine an overload run, if that is desired.

(g) Make the regulation test (Par. **265** and **267**); then since the machine is properly connected, a full-load saturation test may be made for the information of the designer, if required.

(h) The no-load loss may be determined by running the machine idle as a motor (Par. **260**), but the designer will probably want information in regard to the separate losses (Par. **258**). The test results are then worked up, and, if the machine is satisfactory, the insulation resistance is measured and the puncture test made.

**276. Commercial or shop tests.** For standard machines on which the designer has all the information he requires, such a complete test (Par. **275**) is not necessary. The machine should be run idle at normal speed and voltage to make sure that the no-load losses are not too high due to poor material or poor construction, and that the excitation is not too large or too small. The armature and field coil resistances are checked with the calculated values. The machine is run for an hour at 25 per cent. overload to test the mechanical construction and then run idle at 50 per cent. above normal voltage to test the insulation between turns. The speed may be increased during this latter test. The insulation resistance is then measured and the puncture test made. For further information see the series of articles on shop testing by R. E. Workman in Vol. I of *Electric Club Journal*.

## CONVERTERS AND DOUBLE-CURRENT GENERATORS

### SYNCHRONOUS CONVERTERS

BY F. D. NEWBURY, M.E.

#### GENERAL THEORY

**1. Comparison with separate synchronous motor and direct-current generator.** The theory of the synchronous converter is best explained by the similarity of the converter to a synchronous motor driving a direct-current generator. The converter combines the characteristics of both motor and generator in the single armature winding. This winding is provided on one end with a commutator as in a direct-current generator, and on the other with collector-rings and taps to the winding as in a revolving-armature synchronous motor. Alternating current is supplied through the collector-rings, and with no direct-current load the synchronous converter operates purely as a synchronous motor. Its speed is determined by the frequency and number of poles and the flux is fixed by the impressed voltage, just as in a synchronous motor.

**2. Excitation.** In the synchronous converter, as in the synchronous motor, the magnetic flux and the corresponding net exciting ampere-turns are determined solely by the impressed voltage. If it is attempted to vary the exciting ampere-turns and flux by variation of the main field excitation, the latter variation is neutralized by an equivalent change in excitation brought about by a change in phase and value of the armature current, so that the flux and net excitation remain constant. Increased excitation in the main field winding produces a leading current in the armature (leading with respect to the line voltage) which, in the majority of transmission lines serving synchronous converters, is beneficial to line power-factor and voltage. Conversely, under-excitation produces a lagging current which is detrimental to the power-factor and voltage of such lines.

**3. Ratio of alternating voltage to direct-current voltage.** Assuming the synchronous converter to be operating without direct-current load, it will be clear that the direct-current voltage between brush arms will, through the action of the commutator, have a value equal to the maximum instantaneous value of the alternating voltage, giving proper consideration to the relative points in the armature winding to which, at any instant, the brushes and collector-rings are connected. In the single-phase, two-phase, and six-phase diametrically connected converters, the direct-current brushes and collector-rings are connected to equivalent points on the armature winding, so that the ratio between the alternating and direct-current voltages is simply the ratio between the effective and the maximum alternating voltages. In the three-phase converter, the collector-rings are connected to points 120 electrical degrees apart, while the direct-current brushes are connected to points 180 electrical degrees apart, so that the voltage ratio is affected by this difference. The theoretical ratios are shown in Par. 4. See Par. 35 and Figs. 9 to 14, inclusive, for further information.

These theoretical ratios are based on the assumptions that the impressed alternating-current wave form and the counter e.m.f. wave form of the converter are both sine-waves, that there is no loss in the converter, and that the direct-current brushes are at the no-load neutral position. Variations in wave form are small in commercial circuits and apparatus. The effect of the resistance of the windings, brushes, and brush contact is appreciable, and may vary the ratios (Par. 5) from 2 to 4 per cent. Changes in brush position,

Digitized by Google

even within the small limits permitted by commutating conditions, may affect the ratio 1 per cent. A lagging current in the converter winding has the same effect as narrowing the pole-face and will thus increase the ratio of alternating voltage to direct-current voltage. In general, therefore, actual ratios are slightly higher than the theoretical ratios (Par. 4), assuming conversion from alternating to direct-current.

**4. Table of Theoretical Voltage Ratios**

| Number of converter phases | Ratio of alternating voltage |
|---|---|
| Single-phase | 0.71 of direct voltage |
| Two-phase | 0.71 of direct voltage |
| Three-phase | 0.61 of direct voltage |
| Six-phase double delta | 0.61 of direct voltage |
| Six-phase diametrical | 0.71 of direct voltage |

**5. The theoretical current ratio,** neglecting the losses and assuming 100 per cent. power-factor is the inverse ratio of the alternating and direct-current voltages (Par. 4). This follows from the equality of the alternating-current input and direct-current output. From this standpoint, but including the effect of the losses, the current ratios are given by the following formula:

$$I_a = \left(\frac{1}{Eff}\right) Y I_d \qquad \text{(amps.)} \qquad (1)$$

in which expression the symbol $I_a$ represents the value of the alternating current and $I_d$ the value of the direct current. $Eff$ represents the efficiency. $Y$ is equal to twice the square root of two divided by the number of collector-rings. Values of $Y$ are given as follows:

| No. of phases | Value of $Y$ |
|---|---|
| Single-phase | 1.41 |
| Two-phase | 0.707 |
| Three-phase | 0.940 |
| Six-phase | 0.470 |
| (Both double-delta and diametrical transformer connections.) | ..... |

For all practical purposes an average efficiency of 94 per cent. may be assumed, in which case the current ratios will be as shown in Par. 6. These simple ratios are very easily remembered and are convenient for approximate calculations.

**6. Table of Approximate Current Ratios**

| No. of phases | Alternating current per terminal |
|---|---|
| Single-phase | 1.50 times direct current |
| Two-phase | 0.75 times direct current |
| Three-phase | 1.00 times direct current |
| Six-phase | 0.50 times direct current |

**7. Actual current ratio.** Since the current ratios given in Par. 6 are based on theoretical voltage ratios (Par. 4) the actual ratios will vary from 2 to 4 per cent. from those of Par. 6. In specific cases where exactness is desired, the current can be determined most conveniently from the direct-current output, actual alternating voltage, actual efficiency and power-factor using the following formula:

$$\text{alternating current (per terminal)} = \frac{K.W. \times 1000}{E_a \times Eff \times Y \times P.F.} \quad \text{(amp.)} \qquad (2)$$

Digitized by Google

Where $E_a$ is the alternating voltage. Values of $Y$ are given as follows:

| Number of phases | Value of $Y$ |
|---|---|
| Single-phase | 1.00 |
| Two-phase | 2.00 |
| Three-phase | 1.73 |
| Six-phase | 3.00 |

If the efficiency and power-factor are not known, see Par. **28, 38,** and **39** for probable values.

**8. Armature currents and heating.** The current in the converter armature may be considered as made up of: (a) an alternating current, uniformly dividing among the various conductors of the winding, which is necessary to drive the converter as a synchronous motor, and which is determined by the magnitude of the losses; (b) a current flowing from the collector-ring taps to the direct-current brushes, varying widely in value in the different conductors at different positions of the armature with respect to the field poles. The first component is small and in theoretical discussions is usually neglected. The second component for convenience in calculation, may be considered to be a resultant of the instantaneous values of alternating current and direct current in any individual conductor. Fig. 1 illustrates the

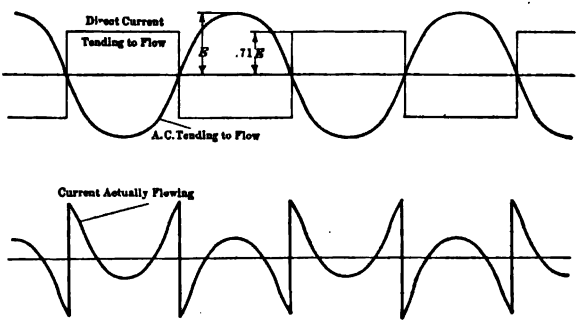

FIG. 1.—Armature current in conductor, 100 per cent. power-factor.

simplest case, namely, that of a conductor midway between alternating-current taps, which are equidistant from pole centres, and with 100 per cent. power-factor alternating-current input. This diagram clearly shows the relation between the effective current actually flowing and the alternating current and direct currents that would flow in separate motor and generator windings, and indicates the fundamental reason for the economy of the synchronous converter due to its single winding.

**9. The ratio of the effective or resultant armature current to the external direct current** varies with the number of phases, or more properly, with the number of connections per pole to the armature winding. The larger the number of such connections, the smaller will be the effective current.

**10. The distribution of the current among the different conductors** at 100 per cent. power-factor is such that the maximum loss occurs in the tap coils and the minimum loss in the coils midway between taps. This is shown in Fig. 3.

**11. The effect of diminishing power-factor on the effective current** is to increase the latter greatly, even with small reductions in power-factor. The effect of decreased power-factor on the distribution of current is

greatly to increase the current and loss in conductors near one side of the tap coils and to reduce the loss in conductors on the other side of the same tap coils. The average effective current and the loss are considerably increased. The effects of power-factor are illustrated by Fig. 2 which shows the same conditions as Fig. 1, except that the power-factor is 86.5 per cent. instead of 100 per cent. It will be seen that the alternating-current wave has been shifted with respect to that of the direct current, thus causing an increase in the effective current. Fig. 3 shows the difference in distribution of losses and difference in average losses with 100 per cent. and 95 per cent. power-factors.

**12. Table showing Relative Converter Losses on Basis of Direct-current Generator Losses taken as Unity**

| 6 | 0.274 | 0.304 | 0.400 | 0.589 | 0.935 | 0.430 | 0.614 | 0.874 | 1.249 | 1.825 |
| 12 | 0.209 | 0.236 | 0.326 | 0.500 | 0.824 | 0.249 | 0.354 | 0.525 | 0.792 | 1.232 |

**13. Losses affecting rating.** Par. 12 shows the relative average losses and maximum loss per conductor compared with those of the equivalent direct-current generator for various phases and power-factors. It shows a large increase, particularly in the maximum loss due to small changes in power-factor. It is this characteristic that limits the use of synchronous converters to operating power-factors near 100 per cent. This table also shows the advantage of a large number of rings. Practically all converters above 200 or 300 kw. are now built with six collector-rings and phases, while 12 rings have been considered for the largest ratings. A distinction must be made, however, between copper loss and rating. This table does not represent relative capacities of the various armatures, since the rating depends on many other factors besides armature coil heating. In general, the **current capacity** of a given armature will be increased by increasing the number of rings and will be reduced by a reduction in power-factor, even slightly below 100 per cent. power-factor, although not to so great an extent as is indicated by a direct comparison of the losses.

**14. The armature reaction of the synchronous converter** is relatively small compared with that of the equivalent direct-current generator on account of the relatively small effective armature current. In this characteristic the converter is very nearly equal to the compensated direct-current generator. In a six-phase converter, the effective armature reaction varies from 7 per cent. to 20 per cent. of the armature reaction in an equivalent uncompensated direct-current generator.*

**15. Commutation in the synchronous converter** offers the same problem as in the direct-current generator, differing only in degree. Due to the smaller effective current the armature reaction and, to a lesser extent, the self-induction, are smaller than in the direct-current generator of equal rating, so that allowable commutation limits are much higher. The synchronous converter, without commutating poles, holds a position between the simple direct-current generator and the direct-current generator with commutating poles and with a compensating pole-face winding. For this reason the commutating poles with their attendant complications were not added to the synchronous converter until long after they had been success-

* Lamme, B. G. and Newbury, F. D. "Interpoles in Synchronous Converters;" *Trans.* A. I. E. E., Vol. XXIX, page 1625.

Digitized by Google

fully used with direct-current generators and motors. During the past 2 years, however, this refinement has been added to the synchronous converter and considerable gains have been made due to its use. In the synchronous converter the commutating-pole winding has approximately 25 per cent. to 40 per cent. of the ampere-turns which are necessary in the equivalent direct-current generator.*

16. **The relation between power-factor and main field excitation** is the same in the synchronous converter as in the synchronous motor or in synchronous generators in parallel. For reasons already stated (Par. 11, 12, and 13), the synchronous converter is not used for operation at low power-factor except at small loads, so that this question is not of practical importance.

17. **Control of direct-current voltage.** Due to the fixed ratio between the alternating voltage and the direct-current voltage, variation in direct-current voltage can be obtained only by three general methods, which are as follows: (a) by varying the alternating voltage; (b) by varying the direct-current voltage; (c) by varying the flux without correspondingly varying the alternating voltage, as in the split-pole converter.

18. **For varying the alternating voltage,** the important commercial methods are: (a) by an induction regulator or regulating transformer; (b) by a synchronous booster; (c) by the combined action of reactance and series field winding.

19. **A regulating transformer** (also called a Stillwell regulator) consists of a transformer with a large number of taps and a dial face plate for connecting the converter terminals to the various transformer taps. The transformers and switching devices are large and expensive, and the switches are subject to rapid deterioration due to sparking while changing the voltage.

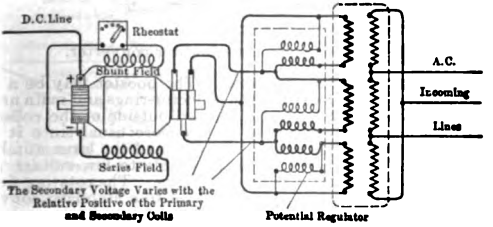

FIG. 4.—Connections of synchronous converter and induction regulator.

The method also has the objection that the voltage cannot be varied by small increments unless an excessive number of taps is provided. In the past this method has been used extensively but, with the development of preferable methods, has been abandoned. An **induction regulator** accomplishes the same result with infinitely small increments and without interrupting the electrical circuit. The induction regulator consists of a stationary winding (usually the secondary) and a rotatable winding (usually the primary), the change in voltage being obtained by rotating one element through part of a revolution, which changes the ratio of the secondary and the primary voltages. It is simply a polyphase transformer with rotatable primary. The connections are shown in Fig. 4. Through suitable relays the alternating voltage may be changed automatically or from a distance. The disadvantages of this method of regulation are the additional floor space and complicated wiring required and the difficulty of designing the induction regulator to withstand the mechanical stresses incident to connecting the converter to the line slightly out of step, and also to withstand short circuits.

20. **The synchronous booster converter** consists of the combination of an ordinary converter with an alternating-current generator having the

* Lamme, B. G. and Newbury, F. D. "Interpoles in Synchronous Converters;" *Trans.* A. I. E. E., Vol. XXIX, page 1625.

Digitized by Google

same number of poles as the converter and having its armature winding connected in series with the converter armature winding. This booster alternator, by a change in its own excitation, varies the voltage applied to the terminals of the converter. The excitation is so arranged that the booster fields and voltage may be reversed without opening the field circuit. The possible variation in voltage is double the rated booster voltage, since it may be added to or subtracted from the line voltage. The connections are shown in Fig. 5. The voltage may be controlled automatically through relays and regulator, or the booster may be series wound, thus automatically compounding the converter. This method of voltage variation has largely superseded the methods previously described, particularly in the larger installations.

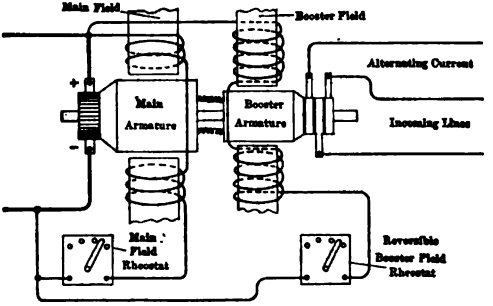

FIG. 5.—Synchronous booster converter.

**21. Types of synchronous booster.** The booster may be a revolving-armature generator located between the collector-rings and main armature, or it may be a revolving-field generator located outside of the collector-rings. The revolving-armature construction is the more usual since it eliminates additional collector-rings and external wiring, and the large number of parallel circuits in the converter winding favorable to low-voltage generation may be conveniently used in the booster winding. The rotating-field booster is sometimes preferable since it may be added to a standard converter with less change in existing parts. There is also less interference with the ventilation of the main armature.*

**22. The application of commutating poles to the booster converter** involves new features due to the motor action, or the generator action, of the converter when the booster is excited. The converter acts as a motor to the extent of the booster output plus all losses, when the booster is excited to increase the direct-current voltage, and, conversely, the converter acts as a generator to the same extent when the booster is excited to lower the voltage. Due to this motor or generator action the effective current in the converter armature varies with the booster excitation as well as with the output of direct current.† If the effective armature current varies, the commutating-pole flux must vary correspondingly if the commutating poles are to be of benefit. This variation is accomplished approximately in one method by providing two windings on the commutating poles, one in series with the armature as in other commutating-pole machines, and the other in series with the booster field winding. The windings are so connected as to assist one another when the direct-current voltage is decreased and to oppose one another when the direct-current voltage is increased. This arrangement of windings provides approximately equal commutating-pole flux and armature flux under all operating conditions except that of no external load coincident

Digitized by Google

with maximum "buck" or "boost." This condition is taken care of by automatically short-circuiting the winding in series with the booster field when the direct current falls below a predetermined value, an equal resistance being connected in circuit simultaneously so that the booster field current is not changed.

The same result may also be accomplished by connecting the commutating field winding in parallel, instead of in series with the booster field winding. The double-dial rheostat used for controlling the excitation of the booster is mechanically connected with a similar rheostat in the commutating-pole exciting circuit. Resistances are placed in series with the shunt commutating-field winding, which are cut in and out of circuit by relays which act successively in accordance with the load on the machine. The advantage of this method is that the current in the commutating-field winding can be changed without affecting the current in the booster field winding; the disadvantage is that two rheostats are required.

FIG. 6.—Variation of converter voltage with reactance in circuit and with varying power-factor.

**23. Automatic compounding.** With reactance in the supply circuit of the converter, the voltage at the collector-rings may be varied through a small range by changing the phase of the supply current. As previously explained, the current phase may be altered by varying the excitation of the main field winding. In practice this is accomplished automatically by providing a series-field winding in addition to the shunt-field winding. The direct-current voltage is varied in the compound-wound converter by the combined effect of the series winding and the reactance in producing a variation of the alternating voltage. While the arrangement of field windings is the same as in the compound-wound direct-current generator, the theory and the action are entirely different. The effect of the reactance in varying the voltage may be seen from the diagrams in Fig. 6. At lagging power-factors the reactance voltage diminishes the line terminal voltage and at leading power-factor it increases the line terminal voltage.*

**24. Heating effect of automatic compounding.** On account of the additional heating at power-factors less than unity, it is customary to operate at low lagging power-factors at light load (when the additional heating is of no consequence) and at leading power-factors only slightly below 100 per cent. at overload.

**25. Conditions affecting direct-current voltage regulation of the compound converter.*** It is apparent that the direct-current voltage regulation of the compound-wound converter depends on many elements internal and external to the converter, and that the change in voltage is limited by the inability of the converter to operate at low power-factor and heavy load. The range of voltage is more restricted and the results are much more difficult to predetermine than in the compound-wound direct-current generator. The voltage range is affected by certain factors which are as follows: (a) the resistance drop between the point of constant voltage and the converter; (b) the reactance drop between the same points; (c) the ratio of armature ampere-turns to shunt-field ampere-turns; (d) the ratio of series-field ampere-turns to shunt-field ampere-turns; (e) the setting of the shunt-field rheostat; (f) the transformer secondary voltage; (g) the total drop through the converter.

**26. Customary values for these factors** (Par. **25**) are as follows: (a) the full-load armature ampere-turns are approximately equal to the no-load shunt-field ampere-turns; (b) the full-load series-field ampere-turns are approximately one-half the armature of shunt-field ampere-turns; (c) the shunt-field rheostat is so set that the lagging component of the line current will be approximately 25 per cent. of the full-load energy component; the shunt-field current will then be about 75 per cent. of its normal no-load 100 per cent. power-factor value under the previous assumptions: (d) the transformer secondary voltage usually is chosen somewhat higher than the correct no-load value to assist in holding up the voltage at overloads.

Under the above conditions, an approximately flat direct-current voltage regulation curve will be obtained with the following values of resistance and reactance measured from the point in the circuit having constant voltage, to the converter collector-rings:

| Resistance drop, per cent. | Reactance drop, per cent. |
|---|---|
| 0 | 4 |
| 2 | 8 |
| 4 | 12 |
| 6 | 16 |

**27. Relation between power-factor and load in compound converters.** With the average conditions stated in Par. **26**, the power-factor will vary with the load approximately as is shown, Par. **28**. With larger overloads—carried for a sufficient length of time to make heating a consideration—the shunt field winding should be further under-excited in order to bring the power-factor nearer unity at the extreme overloads, or the series field should be shunted to reduce the change in power-factor with load.

**28. Table of Power-factor Variation with Load in Compound Converters**

| Load | Power-factor |
|---|---|
| | Per cent. |
| ¼ | 70 lag |
| ½ | 93 lag |
| ¾ | 100 lag |
| 1 | 99 lead |
| Full | 98 lead |
| 1¼ | 97 lead |

**29. The reactance necessary for compounding** may be in the step-down transformers or in separate reactance coils. Where possible, the transformers are designed with the necessary reactance, as this method is

* Bache-Wiig, J. "Voltage Regulation of Compound-wound Rotary Converters;" *Elec. Journal*, Vol. VIII, page 860.

Digitized by Google

lower in cost and requires less floor space and wiring; it is, however, difficult to to design the transformers when the required reactance is more than 10 per cent. It is also more difficult to obtain high reactance in 25-cycle than in 60-cycle transformers, and in the core type than in the shell type (Sec. 6).

**33. The split-pole method of voltage control** utilizes a different principle from any previously discussed. Variation of direct-current voltage is secured, not by a variation in the impressed alternating voltage, but by a change in the shape of the magnetic field, such that the total flux and the direct-current voltage are changed, while the alternating voltage remains substantially unchanged. This is possible because of the fact that in polyphase windings in which the phases are tapped 120 electrical degrees apart, third harmonics and multiples thereof cancel out and do not appear at the 120-deg. terminals. The action of the split-pole converter therefore depends on variations in the field flux distribution which produce third harmonics, in conjunction with taps on the alternating-current side 120 deg. apart. The reason for this will be understood by reference to Fig. 7. It is evident that the armature coils between the 120-deg. taps on the alternating-current side will always include two equal and opposite areas of the third-harmonic variation of flux which neutralize each other and so produce no change in alternating-current wave form. On the other hand, the armature coils between the brushes on the direct-current side, which are 180 electrical degrees apart, will always include three areas of the third harmonic variation in flux, only two of which neutralize each other, leaving one to change the average ordinate of the field flux curve, and, consequently, the direct-current voltage.

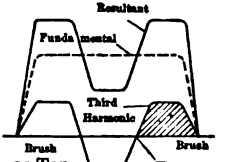

FIG. 7.—Flux distribution in three-part pole, split-pole converter.

With the split-pole converter, the 120-deg. connection on the alternating-current side is preferable; consequently the three-phase delta connection or the six-phase double-delta connection should be used. However, any secondary connection of transformers may be used providing the primary is Y connected and the neutral is not fixed.

Harmonics other than the third and multiples thereof will appear at the alternating-current terminals and will cause a corrective current to flow from the supply circuit through the converter windings so as to neutralize the flux producing these harmonics in the converter. It is desirable, therefore, so to design the converter that the wave form will be as nearly as possible a combination of the fundamental, third and ninth harmonics. In practice this is so nearly accomplished that the effect of the split-pole converter on the supply circuit wave form is negligible.*

**34. Action of the split-pole converter.** When the split-pole converter is operated at a higher voltage than that corresponding to the alternating line voltage, the additional output due to the increased direct-current *voltage* is supplied by an increased *current* on the alternating-current side. This current moreover is a "motor" current dividing in the converter in the same way as the motor current necessary to supply the losses. The value of the effective current is, therefore, considerably increased. At lower voltages the converter acts as an alternating-current generator decreasing the line alternating current, but due to the distribution of the current in the armature the effective current is increased.

**35. Two types of split-pole converter.** The first converters of this type were designed with two regulating poles for each main pole. This arrangement resulted in symmetrical flux and voltage wave forms through-

Digitized by Google

out the entire voltage range, and was favorable to commutation but required machines of comparatively large diameter. The split-pole converters as built at present have a single regulating pole for each main pole. This construction obviously permits a considerable reduction in diameter and cost for a given output, and the detrimental effect of the varying magnetic field in the commutating zone can be compensated for by providing favorable commutating conditions in other respects. The field-flux wave forms and the corresponding voltage wave forms for various voltages, with both the three-part pole and the two-part pole constructions, are shown in Fig. 8.

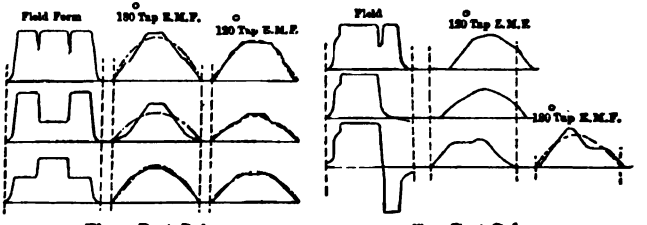

FIG. 8.—Flux-distribution and alternating voltage wave forms in split-pole converter.

Upper curves, max. voltage. Middle curves, mid. voltage. Lower curves, min. voltage.

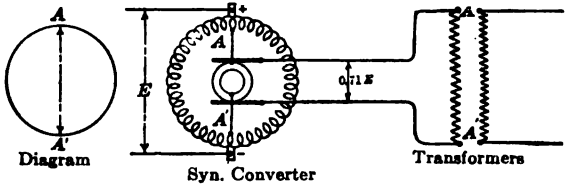

FIG. 9.—Single-phase connections.

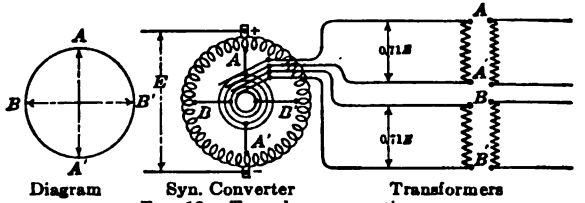

FIG. 10.—Two-phase connections.

**33. Limits of voltage variation with the split-pole converter.** In varying the voltage, the excitation of the regulating poles is increased in the same direction as the excitation of the main poles to increase the voltage, and is reversed to decrease the voltage. The split-pole converter is limited to approximately 20 per cent. variation in either direction, but this is sufficient to cover the majority of applications.

**34. Direct-current booster.**—The direct-current voltage can be varied directly by inserting a booster in the direct-current circuit. This booster may be direct-connected to the converter or driven by a separate

Digitized by Google

motor. It is generally used in the latter form as an addition to existing equipment, since it does not affect the converter either structurally or in respect to operating voltage. All methods involving change in alternating voltage necessitate the operation of the converter at the highest voltage.

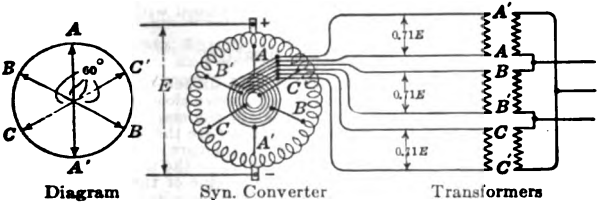

FIG. 11.—Six-phase diametrical connections.

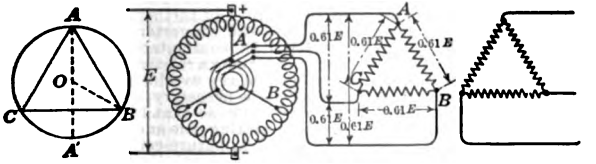

FIG. 12.—Three-phase delta connections.

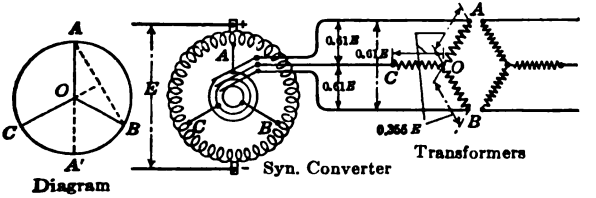

FIG. 13.—Three-phase Y connections.

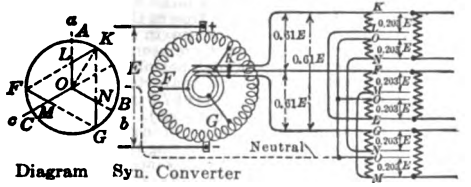

FIG. 14.—Three-phase interconnected Y connections (for 3-wire direct-current circuits).

The weight, floor space and cost of a converter with a direct-connected direct-current booster are greater than the same factors in a converter with an alternating-current booster. A further serious disadvantage of the direct-current booster is the additional commutator, which is equal in current capacity to the converter commutator.

**35. Transformer voltages and connections.** The various transformer connections with voltages commonly used are shown in Figs. 9 to 14, inclusive. Fig. 14 shows the transformer connections necessary when the converter is used to supply three-wire direct-current circuits; this modification in the transformer windings is necessary to avoid magnetic unbalance due to the unbalanced currents obtained with unbalanced loads on the direct-current circuits.

## GENERAL DESIGN

**36. Similarity between converter and direct-current generator.** The general design of the synchronous converter closely resembles that of the direct-current generator. The design of the magnetic circuit is identical; the types of armature and field windings are the same, except for the taps to the collector-rings; the number of armature slots per pair of poles must be some multiple of the number of phases; the design of the electric circuit is the same, except for the reduced value of the effective current. This reduction of effective armature current permits smaller conductors and smaller armature slots—a condition favorable to commutation; it also permits a higher ratio of armature ampere-turns to shunt-field ampere-turns, resulting again in a smaller armature core; and furthermore, it reduces the flux distortion on overload, permitting the converter to carry large momentary overloads without flashing. In commutating-pole converters, the reduced effective armature current permits a relatively small commutating-pole winding, which is favorable to heavy overloads. With the small number of commutating-pole ampere-turns necessary, it is easy to provide sufficient section in the commutating pole so that large overloads can be carried without saturating the commutating pole and thus destroying the equivalence of commutating-pole flux and armature-coil flux. In the direct-current generator this is not true, and commutating-pole saturation is usually a limit to the overloads that can be carried.

There are, however, various requirements in design, due to the rigid relationship between poles and speed, that do not enter into direct-current generator design. Following directly from this relationship, the maximum distance between adjacent neutral points on the commutator of any synchronous converter is a direct function of the frequency and the peripheral speed of the commutator. The peripheral speed of the commutator, in feet per min., is equal to the alternations per min. (cycles per sec. times 120) multiplied by the distance in feet between adjacent neutral points on the commutator surface.

**37. Comparison between 25-cycle and 60-cycle converters.** This simple relationship between poles and speed (Par. 36) is responsible for most of the difference between high-frequency and low-frequency converters. It follows from this law that the distance between neutral points in a 25-cycle converter is 2.4 times the distance in a corresponding 60-cycle converter for the same commutator speed. Thus while ample room is available in the 25-cycle converter for a large number of commutator bars at a low peripheral speed, the reverse is true in the 60-cycle converter. The 600-volt 60-cycle converters that compare in freedom from flashing and sensitiveness with 25-cycle converters have been built only since it became possible to construct commutators of high peripheral speed.

Up to the year 1909, 60-cycle 600-volt converters were usually built with a maximum distance between neutral points of 7.5 in. (19.0 cm.) and a peripheral speed of 4,500 ft. per min. (22.9 m. per sec.). Since that time, through improvements in the mechanical design of commutators, the peripheral speed has been increased to 5,500 ft., increasing the distance between neutral points to 9 in. (22.9 cm.). This greater distance has directly and indirectly improved the operating characteristics. As a direct benefit there is less chance that a flash under a brush will reach to the adjacent brush arm, causing the converter to buck; and, indirectly, the greater distance permits the use of more commutator bars, reducing the maximum voltage between bars and so reducing the danger of an arc spreading from bar to bar. With 9 in. (22.9 cm.) available between neutral points, it is possible to proportion 60-cycle converter commutators as conservatively as those of 25-cycle converters and direct-current generators.

The distance between neutral points becomes a design limitation only with

Digitized by Google

the higher line voltages. At 250 volts the design of the 60-cycle converter has not been handicapped as it was at 600 volts, although it has unjustly suffered in reputation.

At the higher voltages now being used in railway work, the 25-cycle converter approaches the same limiting conditions as the 60-cycle at 600 volts. At 1,500 volts, the 25-cycle converter is theoretically equivalent, in commutator proportions, to the 60-cycle converter at 625 volts.

**38. Table of Weights, Speeds, and Efficiencies for 600-volt 25-cycle and 60-cycle Converters**

| Kw. | Frequency | R.p.m. | Approximate net weight (lb.) | Approximate efficiency at full load, per cent. |
|---|---|---|---|---|
| *300 | 25 | 750 | 10,100 | 95 |
| *500 | 25 | 750 | 15,500 | 96 |
| 1,000 | 25 | 500–750 | 23,000 | 96 |
| 1,500 | 25 | 500 | 39,000 | 96 |
| 2,000 | 25 | 375 | 57,000 | 96 |
| 3,000 | 25 | 214–250 | 92,000 | 96 |
| 4,000 | 25 | 187 | 158,000 | 96 |
| †200 | 60 | 1,200 | 10,500 | 91 |

All designs are of the non-commutating-pole type and will stand 100 per cent. momentary overload.

Where two speeds are given, the weights and the efficiencies apply to

*Will stand 200 per cent. overload momentarily—all other designs will stand 100 per cent. overload.

†Non-commutating-pole type; in all other cases commutating poles are employed.

Digitized by Google

the *lower* speeds. The difference, however, will not be of material importance.

**40. Commutator design** for synchronous converters follows that for direct-current generators except that long high-speed commutators are more frequently used. The longest commutators are built with three V-ring supports, or with two V-ring supports and a central shrink ring. Shrink rings alone are not as effective as either of these constructions for the majority of cases, on account of the large diameters involved. With large diameters, large tangential stresses are produced in the shrink ring by relatively small radial forces. The V-ring construction without shrink rings is generally to be preferred since the commutator can be readily taken apart for repairs and also can be more easily insulated from adjacent parts. A construction embodying four V-rings has been employed to a limited extent; this consists, in effect, of two separate commutators flexibly connected together. The inaccessibility of the middle V-rings is a serious objection to this construction.

Long commutator necks must be braced from each other. This is done by fibre plugs set into each neck, by interlacing heavy twine between the necks, or by roping wooden spacing blocks to each neck.

**41. The ventilation of commutators,** in cases where the necks do not provide sufficient cooling surface and windage, has been most successfully accomplished by attaching radiating vanes about 2 in. square to the outer end of each bar. These vanes not only provide additional cooling surface at the most effective point, but considerably increase the air circulation.

**42. Armature equalizer connections** are used in synchronous converters just as in direct-current generators (Sec. 8) to equalize the effect of the flux under all poles. The collector-rings are also equalising rings, so that the equalizers are usually spaced with respect to the collector-rings. To secure greater accessibility, the equalizer rings are generally located on the collector end of the armature. Special constructions have been developed in order to place the equalizing connections in such a manner that there will be no interference with the collector connections and no increase in the length of the commutator.

**43. Damper windings.** Almost without exception synchronous converters are provided with damper or **amortisseur windings** to prevent hunting (Par. 61). These are usually of the built-up grid type, commonly employed on the rotors of induction motors, consisting of a large number of bars located in slots in the pole-face, and connected on the ends by continuous rings. A cast-copper damper winding is sometimes employed, consisting of relatively few bars of large cross-section in the pole face. In the commutating-pole converters, the end rings are sometimes made in disconnected segments—one for each pole—so that the commutating poles will not be enclosed by the damper winding. If the commutating poles are individually enclosed, changes in the commutating-pole flux are damped, thus preventing the commutating-pole flux from changing as rapidly as the armature current and flux when sudden changes in load occur.

**44. The machine ventilation** problem varies widely in converters for different frequencies and voltages. In high-speed 25-cycle converters of medium output, the armatures are small in diameter and relatively long. Every means is used to increase the natural air circulation. In these machines, heating and commutation are of approximately equal effect in limiting the output. In large 25-cycle converters of both voltages (250 and 600) and in 60-cycle converters for 250 volts, the natural air circulation is ample for the dissipation of the losses, but not excessive. In 60-cycle 600-volt converters and particularly in those of large size, the armatures are of large diameter and narrow, and the peripheral speeds are high. Under these circumstances, the natural air circulation is much greater than is necessary and greatly increases the windage loss. In such machines the natural air circulation is restricted as much as possible by stopping the air entrances in order to eliminate the unnecessary windage loss.

## CHARACTERISTICS

**45. The no-load saturation curves** are very similar to the same curves for direct-current generators. There are two such curves—one with direct-

Digitized by Google

current volts and one with alternating volts as ordinates. From these curves the actual no-load voltage ratio may be determined for any desired voltage.

**46. Heating of synchronous converters** occasions practically no difficulty either in design or in operation under proper conditions of power-factor, etc. The problem, however, varies with converters of different frequencies and voltages (Par. 44).

**47. The overload capacity,** as determined by heating and by flashing, is inherently large, due in great measure to the small armature reaction. The latter is particularly important since it results in small field distortion due to load. Consequently, on sudden changes in load, there is very little increase in voltage between commutator bars or shifting of the flux in the commutating zone, both of which, if present, would tend to cause flashing.

**48. The losses** may be divided into constant losses (with varying load) and variable losses. The constant losses are: core loss; friction and windage losses (including commutator and collector friction); and shunt field and rheostat loss (assuming that rheostat resistance and direct-current voltage remain fixed). The variable losses are: armature copper loss; series-field copper loss; commutating-field copper loss; brush $I^2R$ and surface-contact losses; and load loss.

**49. Additional losses in the synchronous booster converter.** In the synchronous booster converter, the only additional losses at the mid-voltage are the booster armature copper loss and the load loss. At higher voltages, the converter core loss is increased due to the larger "motor" current, and the booster core loss and field copper loss are added. At lower voltages the converter core loss is reduced, since the flux is reduced; the converter copper loss is increased due to the larger "generator" current, and the booster losses are the same as for a corresponding increase in voltage.

**50. Additional losses in the split-pole converter.** In the split-pole converter there are no additional losses at the mid-voltage, but at either lower or higher voltages the converter core-loss is increased, since the flux density is increased (Par. 32 and Fig. 8). The converter copper loss is increased, as in the booster converter, at higher and lower voltages (Par. 31).

**51. Hunting of synchronous converters,** as in other forms of synchronous apparatus, is the periodic variation of the rotor from the true synchronous position with respect to the supply system. During hunting, the rotor is alternately ahead and behind its true synchronous position. In forging ahead, energy is expended in the converter, the latter acting as a motor; in dropping behind, the converter acts as a generator and gives up energy. This alternate motor and generator action is accompanied by a variation in the value of the flux due to the armature reaction, by a fluctuation of alternating-current and power-factor, and by a shifting of the commutating field which causes periodic sparking at the brushes. The frequency of the hunting cycle may often be determined from the frequency of the sparking. Hunting may be caused by periodic variation in the supply frequency, by sudden changes in load, or by excessive line drop. It is more likely to occur in 60-cycle than in 25-cycle converters, because of the greater number of poles and consequently smaller actual angular variation corresponding to the limiting electrical angular variation.*

**52. Hunting may be practically eliminated** by providing suitable **damper** or **amortisseur windings** in the pole faces. Since hunting is accompanied by a shifting of the flux across the pole face, the winding placed in the path of this flux will oppose any such change, and will tend to damp out the oscillations as soon as they begin. Practically all converters are now built with such windings (Par 43). Hunting troubles have also been greatly reduced by the use of generators driven by steam turbines or water turbines in which the angular velocity is much more uniform than in reciprocating engines.

**53. Interruption of energy supply.** If a converter is operating alone

Digitized by Google

or in parallel with other converters supplied from the same alternating-current feeders, the interruption of the alternating-current supply will bring the voltage on the direct-current side to zero, and the converters will stop. However, if there is another source of direct-current connected to the same direct-current bus and not dependent on the same alternating-current feeders interruption of the alternating-current supply will not cause the converter to stop; the direct-current voltage will be maintained and the converter will be driven as an inverted converter. If the shunt field happens to be weak or is interrupted, or if the converter should supply energy to an inductive load on the alternating-current side (such as a short-circuit on the high-tension side of the transformers) the speed will greatly increase. To guard against danger under such conditions, converters are usually provided with a speed limit device, and the alternating-current and direct-current breakers are so interlocked that opening the alternating-current breaker opens the direct current breaker. In addition, the direct-current breakers are sometimes provided with a reverse-current tripping relay. When the alternating-current supply is subject to serious drop in voltage due to short-circuits or other cause, it may be advisable to provide the alternating-current breakers with low-voltage tripping coils. This is particularly necessary with commutating pole synchronous converters due to the flashing that would occur should the converter drop out of step as a result of low voltage, and later start with the brushes down when the voltage resumes normal value.

**54. The speed-limit device** (Par. 52) consists of a pivoted weight rotating with the converter shaft; the centrifugal force acting on the weight is counter-balanced by a spring. The weight moves outward and operates a switch when the predetermined overspeed is reached. The switch closes (or opens) the circuit of the shunt tripping coil of the direct-current breaker.

## GENERAL APPLICATIONS

**55. Comparison of efficiency with that of a motor-generator set.** The efficiency of a 60-cycle converter including its transformers will be from 3 per cent. to 5 per cent. higher than an equivalent synchronous motor-generator set without transformers. The 25-cycle converter shows a further gain in efficiency over the motor generator set of from 0.5 to 1.0 per cent. If the line voltage is above 13,200 volts, transformers will usually be required with the motor-generator set as well as with the synchronous converter, so that the difference in efficiency in favor of the latter will be further increased by 2 per cent. This higher efficiency of the converter is such an important advantage that it is sufficient alone to justify the use of synchronous converters wherever possible.

**56. Comparison of required floor space with that of a motor-generator set.** The floor space required by 60-cycle converters and transformers is approximately equal to the floor space required by 60-cycle motor-generator sets of compact design. The fact, however, that the transformers may be placed in some remote location makes the arrangement of synchronous converters and transformers more flexible and gives them in many cases the advantage of reduced floor space.

**57. Comparison of cost with that of a motor-generator set.** The combined cost of synchronous converters and transformers is approximately equal to the cost of synchronous motor-generator sets without transformers, assuming a motor voltage of 2,300 volts or lower. For higher alternating voltages the motor cost increases appreciably, making the comparison favorable to the converter equipment. With alternating pressures above 13,200 volts, transformers are necessary with the motor-generator set as well as with the synchronous converter, so that the cost of the converter equipment is relatively still lower. With 60-cycle apparatus under 200 kw. capacity and alternating voltages of 2,300 volts and lower, the comparison is somewhat in favor of the motor-generator set, while with larger apparatus the comparison is somewhat in favor of the synchronous converter. In few cases, however, will there be sufficient difference in cost alone to determine the choice of the apparatus.

**58. Comparison of reliability with that of a motor-generator set.** The design and construction of synchronous converters has been standardised to such an extent that in respect to reliability the comparison is mainly concerned with the number of machines involved. Compared with a three-

Digitized by Google

unit motor-generator set consisting of a synchronous motor, direct-current generator and direct-current exciter, the single unit converter has a decided advantage. The comparison between the motor-generator set and the booster converter is apparently less favorable on account of the additional booster generator, but there are so few troubles that can reasonably be expected in a relatively small low-voltage alternator that the difference is more apparent than real.*

**59. Comparison of voltage control with that of a motor-generator set.** In this characteristic the synchronous motor-generator set has an advantage over the synchronous converter. The independence of alternating and direct-current voltage in the motor-generator set may justify its use as alternating-current circuits in which the voltage fluctuates badly and where it is essential to maintain steady direct-current voltage. Even under such conditions of fluctuating alternating voltage it is considered preferable, by some engineers, to employ the converter and obtain the desired steady direct-current voltage by means of a regulator.†

**60. Comparison of power-factor control with that of a motor-generator set.** The motor-generator set, including a synchronous motor, may be designed to correct power-factor more economically than can the synchronous converter. For this reason, the motor-generator set is usually employed where considerable power-factor correction is necessary.

**61. For railway service** compound-wound synchronous converters are generally used, sufficient reactance being placed in the alternating-current supply circuit to obtain the necessary voltage regulation. For this service on 25-cycle systems, synchronous converters are used to the practical exclusion of motor-generator sets and other forms of conversion apparatus. On 50-cycle and 60-cycle systems, the use of motor-generator sets, and in Europe the use of motor converters has, in the past, been more general; but even for these higher frequencies the use of the synchronous converter is rapidly growing.

**62. For lighting and power service,** the shunt-wound converters with induction regulators or the more specialized forms of split-pole and booster converters are used. On the larger 25-cycle systems, the use of converters is general. On 60-cycle systems, their use, particularly in the booster form, is rapidly growing, due mainly to the gain in efficiency.

**63. The synchronous converter can be used to supply 3-wire direct-current circuits** without any structural change, except in the case of compound-wound or commutating-pole converters, in which the series windings on alternate poles are connected in the positive and negative leads so that unequal currents in these leads will not affect the magnetization of the converter. See Par. 35 and Fig. 14 for the transformer connections necessary to obtain the neutral lead. The synchronous converter will operate under extreme differences of current value in positive and negative leads with very small differences in voltage between the outside leads and the neutral lead. For example, a 1,000-kw., 60-cycle, 280-volt commutating-pole booster converter, operated with full-load current in the positive lead and half-load current in the negative and neutral leads, had a difference of only 1 volt in the pressures from neutral to positive and neutral to negative leads. The same converter, operated with full-load current in the positive and the neutral leads and zero current in the negative lead, had a difference of 4 volts in the pressures from neutral to positive and neutral to negative leads. Without the resistance drop of the booster armature winding, the voltage balance would have been still better.

**64. For electrolytic work,** either shunt-wound converters without means for varying the voltage, or the same types of variable voltage converters as used for lighting service, are generally employed.

## OPERATION

**65. Alternating-current self-starting.** The synchronous converter may be started as an induction motor if alternating current at reduced vol-

tage is applied to the collector-rings. The armature winding acts as the primary and the squirrel-cage winding imbedded in the pole faces acts as the secondary. For the smaller converters one starting voltage only is required. The middle terminals of a double-throw switch are connected to three of the collector-rings, one set of outer terminals is connected to the starting-voltage taps of the transformers and the other set of outer terminals is supplied with the full voltage of the line. With six-phase converters three leads are carried direct from the transformer to the converter, and three through the main and

starting switches. With the largest converters, it is usual to employ two starting voltages for which two double-throw three-pole switches are required. The connections for this arrangement are shown in Fig. 15.

**66. Field "break-up" switch.** During the starting period the field winding has voltages induced in it of magnitudes depending upon the ratio of armature and field turns. To prevent a dangerous induced voltage in the field winding, it is usual to open the field circuit in several places during the starting period by means of a multi-point double-throw switch, which is usually located on the frame of the converter. Appreciable voltage rise in the field circuit may also be prevented by closing the field circuit during start-

ing. This method is beginning to be employed because it only requires a double-pole double-throw field switch which may be conveniently located on the starting panel adjacent to the main switch.

**67. Series-field switch.** If a series-field shunt is used, a switch is usually provided for opening the closed circuit formed by the series field and its shunt. If this low-resistance circuit were left closed, the single-phase current induced in it would tend to decrease the starting torque. This effect, however, is small. The detail connections of the direct-current side of the converter are shown in Fig. 16.

Digitized by Google

**68. Reversed polarity with alternating-current self-starting converters.** In this method of starting with a self-excited field winding, there is no method of predetermining the polarity of the direct-current terminals. However, if the converter falls into step with the wrong polarity, the machine may be forced to "slip a pole" (if the armature is connected to the low-voltage taps) by reversing the field switch. When the voltmeter indicates that the voltage is reversed, the field switch should be brought back to its original

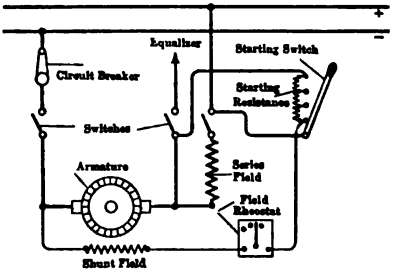

FIG. 17.—Direct-current self-starting connections.

position. In some converters, the field set up by the alternating-current may be so strong even at the lowest starting voltage that the converter cannot be made to "slip a pole" by reversing the field. Under these circumstances it is necessary momentarily to open and close the starting switch, repeating this operation until the correct polarity is obtained.

**69. Direct-current self-starting.** The converter may be started as a direct-current shunt-wound motor. The current flow at starting is limited by an adjustable resistance controlled by a multi-point starting switch. The connections for this method are shown in Fig. 17.

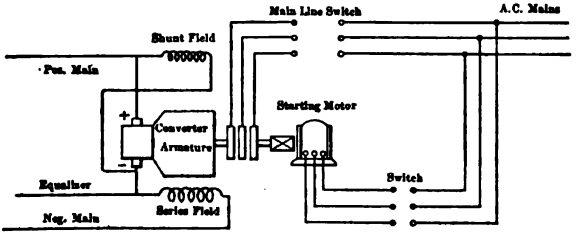

FIG. 18.—Alternating-current motor-starting connections with manual synchronizing.

**70. Alternating-current motor starting.** A motor usually of the induction type is mounted on the converter shaft. The motor has fewer poles than the converter and, therefore, a higher synchronous speed. In starting, the motor is usually connected directly across the line. The connections for this method are shown in Fig. 18.

A modification of this method has recently been brought out by Dr. Rosenberg of Manchester, England, and by James Burke* in this country, which consists in connecting the starting-motor windings in series with the converter armature. This limits the starting current to a low value, and the

alternating current in the converter armature causes it to lock automatically in synchronism.*

An older modification of the simple motor-starting method, designed to eliminate the necessity for synchronizing, is the addition of reactance in the main circuit as shown in Fig. 19. When the starting motor has brought the converter armature near synchronous speed, the main-line switches are closed with the reactance in circuit. The resulting current in the converter armature causes it to lock in synchronism, after which the reactances should be short-circuited.

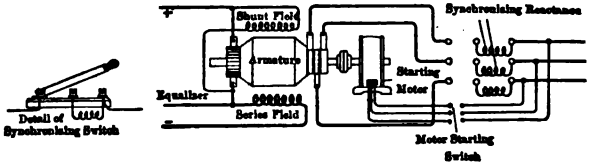

FIG. 19.—Alternating-current motor-starting connections self-synchronizing with reactance.

**71. Starting small single-phase converters.** A method of starting, adapted to small single-phase converters, has been developed by the Wagner Electric Manufacturing Company, and is used on the small single-phase converters built by that company for charging electrical vehicle batteries, the supply of direct current for moving-picture arc lamps and similar purposes. A special distributed field winding is provided on the stator, so connected that with the double-throw starting switch in the starting position the converter starts as an alternating-current series-wound commutator motor. When the starting switch is thrown to the running position, the alternating-current leads are transferred to the collector-rings, the main-field winding is connected in shunt with the main direct-current armature leads and a part of the field winding is short-circuited to act as a damper winding. See Sec. 17, "Garage Equipment."

**72. Methods of synchronizing.** With the simple motor-starting method, or with the direct-current self-starting method, the converter must be synchronised with the alternating-current supply circuit before the main-line switches can be closed. The theory and methods involved are the same as employed in synchronizing two alternating-current generators (Sec 7). Lamps or specially designed instruments (Sec. 3) may be used for indicating synchronism, as with generators.

With the motor method of starting, the running speed of the starting motor should, in general, be higher than the synchronous speed of the converter. The speed may be brought down to synchronous speed by increasing the load on the converter. This can be accomplished by increasing the voltage, thereby increasing the converter losses, or by connecting a resistance across the alternating-current terminals of the converter. Small adjustments in speed may be made by alternately opening and closing the starting-motor switch.

With the direct-current self-starting method, the speed regulation for synchronizing is obtained by varying the converter shunt-field current. The series-field circuit is opened to insure more constant speed under the condition of varying armature current. To prevent a rush of current at the instant of synchronizing, it is usual to leave a small amount of resistance always in the starting-rheostat circuit.

**73. Comparison of different starting methods.** The alternating-current self-starting method is used in most cases on account of its simplicity and its automatic synchronizing feature. Its principal defects are the uncertainty in polarity and the large starting current required. In most cases wrong polarity can be corrected by means of the reversing field switch (Par. 66), and the amount of starting current is of importance (aside from the momentary line drop) only when the converter rating approaches the rat-

* Report of Com. on "Electrical Apparatus," National Electric Light Asso. Proceedings, 1914.

Digitized by Google

ing of the alternator supplying it. With commutating-pole synchronous converters, the simplicity of this method is decreased by the necessity of lifting the direct-current brushes. The presence of the steel of the commutating poles greatly increases the armature flux during starting, which causes destructive sparking at the direct-current brushes. To avoid this objectionable feature, commutating-pole converters are provided with a special device for lifting all but two of the brushes (which indicate polarity) during the starting period.

The advantage of the alternating-current motor method of starting is the small current required and the certainty of obtaining correct polarity; the principal disadvantage is the necessity for synchronising. This disadvantage is overcome by the Rosenberg method or by the use of separate reactance coils (Par. 75). As compared with the alternating-current self-starting method, this method is somewhat more complicated and the necessary apparatus is more expensive. In some cases, however, where small values of starting current are imperative, it is the only method which will meet the requirements.

The direct-current self-starting method can only be used where direct current in sufficient amount is always available. It is very often used in large city lighting and railway substations. It has the advantage of minimum starting current and the absence of disturbances on the alternating-current supply system (which is particularly important on underground distribution systems). As with the simple alternating-current motor method, it has the disadvantage of necessitating manual synchronising. This disadvantage has been overcome in some cases by combining the direct-current and the alternating-current self-starting methods. The converter is started by means of direct current, and when a speed near synchronous speed has been reached, the alternating-current switches are closed.

**74. Parallel operation.** When two or more converters are connected to the same low-tension bus on the alternating-current side and to the same bus on the direct-current side, the total direct-current load will divide among the several converters in the inverse ratio of the counter e.m.fs. of the converters and the resistances of the circuits. If two or more converters are so connected, the alternating-current and the direct-current bus bars close the circuit through any pair of converters; hence if the counter e.m.fs. of the two converters vary even slightly, considerable current will circulate between them. The counter e.m.fs. of different converters are seldom exactly the same, and the resistances, made up mainly of the direct-current brushes and brush contacts, are extremely variable—even in the same converter at different times. For these reasons it is not considered good practice to operate converters in parallel on both the alternating-current and the direct-current sides. Separate banks of transformers are usually provided—one for each converter. These not only open the circuit between converters, but also provide means for correcting slight differences in the voltage ratio of different converters.

**75. Division of load on the direct-current side** is controlled by the same factors as in direct-current generators, and in addition by factors peculiar to the synchronous converter. Division of load is controlled by the voltage, so that all factors affecting voltage affect parallel operation. Parallel operation of shunt-wound converters, with or without auxiliary means for controlling the voltage, is as simple as parallel operation of shunt-wound direct-current generators. With compound-wound converters, equalizer leads are necessary as in direct-current generators. (Sec. 8.)

**75. Corrections for improper division of load.** With two converters operating in parallel on the direct-current side, one of which takes less than its proportionate share of the load, the load may be equalized by one or a combination of the following adjustments:

**(a) Adjustment of the series-shunt resistance.** The shunts on the series-field windings can be adjusted, decreasing the resistance of the shunt, if possible, on the overloaded converter or increasing the shunt, on the underloaded converter. It should be borne in mind, however, that changing the ampere-turns in the series field by changing the shunt resistance also changes the resistance of the complete series-field circuit. This change in shunt resistance must be compensated for by a corresponding change in the resistance of another part of the series-field circuit, so that the resistance of

Digitized by Google

the total circuit remains unchanged. From another standpoint, a shunt on one converter series field may be considered to be a shunt on both series fields, the effect varying only by reason of the fact that the resistance of the leads and busses is added to one shunt circuit and not to the other (Sec. 8).

(b) **Insertion of resistance in leads between series-field and equalizer bus.** If the relative ampere-turns are correct but the series-field resistances are differently proportioned, the resistance of the leads between the series field and the equalizer bus may be changed to compensate for a difference in the series-field resistances. The resistance in the series circuit of the converter taking more than its share of the load should be increased. This adjustment varies the resistance of one series field without introducing a third parallel circuit between the equaliser and the main bus. Adjustment by this method is less complicated than an adjustment of the series-shunt resistance.

(c) **The transformer ratio can be changed.** This increases the voltage by the same amount throughout the range of load, and will not correct for an unequal division which changes with the total load. An increase in no-load voltage of one converter will cause, at lighter loads, a greater increase in proportionate load on that converter.

(d) **The reactance can be increased in the circuit of the lightly loaded converter,** which will raise its direct-current voltage and cause it to carry more nearly its proper share of the load. This method is similar in effect to an increase in the number of series-field turns, but the effect is obtained at the expense of a greater range in power-factor. It sometimes happens that the reactances of converters in parallel are worked at different saturations, with the result that the reactance voltages of the two converter circuits will have different ratios at light and at heavy loads. Such a relation will cause the converter with the more highly saturated reactance to take less than its share of the load at heavy loads.

(e) **The relative shunt-field currents of the two converters can be changed.** The converter having the smaller ratio of series-field ampere-turns to armature ampere-turns should have its shunt-field current increased. This will increase its no-load voltage (on account of change in power-factor) and cause it to take a greater share of the load at light loads. The voltages will tend to equalize as the load increases, a correct division being obtained at only one value of the load.

**77. Load-division study.** Since there are so many variables affecting load division, it is important to make a careful and systematic study of the particular case before making any changes. Such a study should be conducted as follows:

(a) Adjust the transformer ratios so that at no-load and with the shunt field adjusted to give equal power-factors, all converters have the same no-load direct-current voltage.

(b) The series fields should be adjusted by shunts so that the ratio of series-field ampere-turns to armature ampere-turns is the same.

(c) The resistances of the series fields (including shunt) plus the resistances of the leads from the series fields to the main bus (positive or negative) should be so adjusted that the resistances are inversely proportional to the rated capacities of the converters.

(d) The reactances should be adjusted, if possible, so that the reactance volts of the various circuits throughout the range of load are equal. If they cannot be made equal, the series ampere-turns should be greater in the converter having the smaller reactance, to afford an approximate compensation.

It is only possible to obtain correct division of load and equal power-factor on all converters when the machines are properly proportioned with respect to all four elements, namely: the transformer ratio, the series-field ampere-turns, the series-field resistance and the reactance.

**78. Interruption of alternating-current supply by circuit breaker in substation.** Under such conditions, if the converter is connected to another source of direct current, the converter will "motor" unless the direct-current breaker is opened by interlock with the alternating-current breaker (Par. 53) or by a reverse-current relay. A compound-wound converter will run in the same direction when the direct-current power is reversed, the

Digitized by Google

current in the series winding will be reversed (unless there are several converters in the same station connected to an equaliser bus), and the current in the shunt winding will remain the same in direction. With a single converter in a substation which is connected to other converters in other substations on the direct-current side, the converter will increase its speed due to the reversed series field. It may also increase its speed if the shunt field is adjusted for less than 100 per cent. power-factor. The increase in speed from the reversed series field will not be serious unless there is a circuit connected to the alternating-current side which will provide a load. Under these conditions the overspeed device will operate, thereby opening the direct-current breaker.

**79. Interruption of alternating-current supply outside substation.** In this case an interlock between the substation alternating-current and direct-current breakers will not operate to open the direct-current breaker, and reverse current or overspeed must be depended upon to protect the converter.

In case of interruption of alternating-current supply the converter should be manually disconnected from the direct-current lines (if this is not done automatically) and the switches on the alternating-current side opened for starting.

**80. Commutating-pole converters require more complete protection from low alternating voltage** because of the excessive sparking at the commutator which is encountered when the converter is not in phase with the supply circuit. If the alternating voltage is lowered momentarily by a short-circuit or other cause, the converter may fall out of synchronism. When the voltage is restored the converter will not be in phase and the sparking may be sufficient to make the converter "buck." The conditions are similar to those which exist when starting the converter with the brushes down.

**81. Protection of high-voltage converters.** High-voltage converters (1,200 volts and above) should be more completely protected from abnormal conditions than low-voltage converters on account of the more destructive nature of the "bucking" when once started.

**82. Sparking at the brushes** may be due to any of the following causes: (a) brushes incorrectly set with reference to the neutral point. Correct setting is of particular importance in commutating-pole converters; (b) brushes of improper characteristics; (c) defective electrical design; (d) hunting; (e) severe overloads or extreme variation in load; (f) in non-commutating pole converters, low alternating voltage with large direct-current loads; (g) brush holders insufficiently supported; (h) brushes stuck in holders or inaccurately fitted to commutator; (i) improper brush tension; (j) rough commutator due to high bars, to high mica or to flat spots.

**83. Bucking or flashing** may be brought about by any condition causing excessive voltage in the coils short-circuited by the brush or between adjacent commutator bars, or may be caused by abnormally low-surface resistance on the commutator between adjacent brush arms. Any condition tending to produce poor commutation increases the likelihood of bucking. Excessive voltage under the brush is usually caused by short-circuits of varying degree. Any direct-current machine will flash if short-circuited at its terminals and the direct-current voltage is maintained. Short-circuits in service usually occur on the line, so that some resistance exists between the "short" and the machine, thereby limiting the current. Excessive voltage between commutator bars is caused directly by increased line voltage, or is indirectly caused by extreme current overloads which distort the field flux. Increased line voltage may be due to disturbances on the high-tension distributing system induced by lightning, switching, short-circuits, etc. A decrease in the insulation strength between brush arms may be due to the presence of conducting gases formed by a relatively small flash or of foreign substance such as dirt or water. Ordinary types of circuit breakers do not act quickly enough to protect machines from abnormal changes in current or voltage. On short circuits, for example, the current increases far beyond the setting of the breakers before the circuit is finally opened.

**84. Reactance used as a protection against short circuits.** Shunt-wound synchronous converters may be protected from the effects of short

Digitized by Google

circuits by inserting reactance in the alternating-current leads. Twenty-five per cent. reactance, for example, will cause a drop in alternating voltage to approximately zero with four times full-load current, but the drop at full-load current will not be objectionable.

## TESTING

**85. The tests ordinarily made on synchronous converters** are as follows: (a) resistance measurements; (b) polarity determination; (c) ratio of voltages; (d) core-loss and saturation test; (e) alternating-current short circuit or synchronous-impedance test; (f) starting tests; (g) voltage regulation test; (h) temperature tests; (i) commutating-pole saturation test.

**86. Measurement of resistance.** Resistances may be measured either by the bridge method or by the use of ammeter and voltmeter as in direct-current machines. It is customary in obtaining the armature resistance to measure the resistance both on the direct-current side between the proper commutator bars, and on the alternating-current side between the corresponding slip-rings.

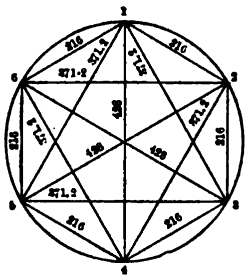

FIG. 20.—Diagram of converter voltages between collecter-rings.

**87. Determination of polarity.** The correct polarity of the field windings is determined in the same manner as for direct-current generators. The relative polarity of the shunt and the series windings in the compound-wound converter is also determined the first time the converter is under load.

**88. Determination of voltage ratio.** In order to determine whether the various taps from the armature winding have been brought out correctly and connected to the proper rings, readings of voltages between each ring and every other ring are taken. During the test the direct-current voltage is held constant at some convenient value. The armature winding is usually connected to the collector-rings so that adjacent rings have the minimum voltage possible between them. Under these conditions the voltage between adjacent rings is given by the following formula, $N$ being the number of rings:

$$E_{ac} = \frac{E_{dc}}{1.415} \left(\sin \frac{180 \text{ deg.}}{N}\right) \quad \text{(volts)} \qquad (3)$$

A convenient method of checking the values obtained on test is to construct a diagram such as that in Fig. 20. The numbers outside of the circle represent the collector-rings. The voltages shown were actually obtained from a 600-volt six-ring converter.

**89. Determination of core-loss, saturation, friction and windage losses.** This test is made either by driving the converter by a small direct-current motor or by driving the converter itself as a direct-current shunt-wound motor. The test is the same as the corresponding test of a direct-current generator except that alternating voltages are obtained as well as the direct-current voltage, in order to obtain the actual voltage ratio. If the converter is self-excited during the test, the measured loss must be decreased by the field-winding and rheostat losses. The **brush friction** is determined by the difference in the measured losses with the brushes down and the brushes up. This reading is of no value unless the commutator has a good polish and the brushes are well seated. The **friction and windage losses** are determined by the difference in measured converter losses with the brushes removed, and with the driving motor running disconnected from the machine under test.

**90. Starting tests.** With the alternating-current self-starting method, a test is made to check the sufficiency of the starting voltage to bring the converter up to synchronous speed. It is customary to measure the voltage, current and time required to reach synchronous speed. With the induction-motor method of starting, the test is made to ascertain whether the load on the starting motor (provided by the converter) is such as to permit it to

Digitized by Google

operate sufficiently near the converter synchronous speed at the normal converter voltage, so that synchronising will be possible. If the normal losses of the converter are not sufficient to reduce the starting-motor speed to the converter synchronous speed, it is necessary to determine the additional load required.

**91. The voltage-regulation test** can be made only when the entire equipment of transformers and reactances to be installed with the converter is available. Even under such circumstances the test must be made on the basis of constant alternating voltage on the high-tension side of the transformers. This is rarely, if ever, true in practice, so that the test unless made after installation is of little value and is seldom made. Furthermore, there is no object in adjusting the series winding of a converter except in conjunction with all other converters with which it is to operate in parallel on the direct-current side. With compound-wound converters, the alternating voltage should be adjusted to the desired value, and the shunt field of the converter should be adjusted to give the correct voltage at no load. If the transformer ratio is correct, this will require considerable lagging current, which may be obtained by under-excitation. Load is then placed on the converter and the desired full-load voltage is obtained by adjusting the series-field shunt. This test is never made with shunt-wound converters since a slightly drooping voltage characteristic would always be obtained, and there is no means within the converter of modifying it. With converters designed for wide voltage ranges, it is customary to observe the operation at the maximum and minimum pressures to insure that there is sufficient range in the field windings and rheostats to obtain 100 per cent. power-factor at all voltages, and that satisfactory commutation is obtained throughout the voltage range.

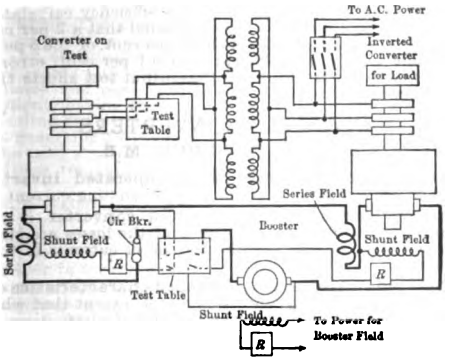

FIG. 21.—Loading-back temperature-test connections.

**92. The temperature tests** at the factory are performed either by direct loading on resistances or by "**loading back**" on a similar converter or power circuit. In the loading-back method (using a similar converter), the losses can be supplied from either the direct-current or alternating-current sides as is found convenient. The alternating-current sides of the machine under test and of the test machine may be connected together by a complete metallic circuit, or through transformers having a one-to-one ratio. The latter arrangement is preferable, as conditions are thus made more stable and can be more easily controlled. The connections for such a test are shown in Fig. 21. When the machines under test are compound-wound, it is necessary to reverse the series field of the converter running inverted. In Fig. 21 the losses are supplied partly from the alternating-current side and partly by a booster in the direct-current side. Temperature tests are usually made with 100 per cent. power-factor at the converter collector-rings. To obtain this

Digitized by Google

condition, the shunt field should be adjusted for the proper no-load voltage, and the series field shunted to give 100 per cent. power-factor, that is, a minimum value of armature current, at the tested load.

**93. Commutating-pole saturation test.** On commutating-pole converters this test is made to determine the sensitiveness of the converter to proper adjustment of the commutating-pole ampere-turns. The converter is so connected that it can be loaded with the commutating poles separately excited, in order that the excitation can be adjusted. For various loads and, in variable voltage converters, for various voltages, the minimum and the maximum commutating-pole excitations are determined between which satisfactory commutation is obtained.

**94. Determination of efficiency.** Efficiencies are usually determined by separate measurements of the various losses. This method does not derive the true efficiency, as the so-called load losses or stray losses cannot be included by direct measurement. Such losses, however, in converters are small and no appreciable error is introduced by omitting them. They are less in low-frequency converters than in high-frequency converters. If the true efficiency is required, it can be measured only by an input-output load test, which may be made with the converter carrying a resistance load or loaded back on another converter. On account of the relatively small losses involved and the large number of instruments to be read, such a test can be made satisfactorily only under laboratory conditions where the power input and output are absolutely steady, and where carefully calibrated instruments are read by skilled observers. Unless the test can be made under such conditions more accurate results will be obtained by calculating the efficiency from the separate measurable losses, and including a reasonable allowance for the load losses.

The reason for the greater accuracy of the efficiency calculated from the separate losses is apparent when it is remembered that a 2 per cent. error in the measurement of the losses results in only 2 per cent. of the 5 per cent. losses (using 95 per cent. as the true efficiency) or 0.1 per cent. error in the efficiency, while 2 per cent. error in the input-output test affects the efficiency by an equal percentage.*

## INVERTED CONVERTERS

### BY F. D. NEWBURY, M.E.

**95. Any synchronous converter can be operated inverted;** that is, it can be used to convert direct current into alternating current.

**96. The internal action of the inverted converter** is the same as that of the synchronous converter except that the losses are supplied from the direct-current side, so that the distribution of currents in the armature is slightly different.

**97. The inverted converter has the speed characteristics of a direct-current motor** instead of a synchronous motor, except that when the converter operates in parallel with another source of alternating current the speed is controlled by each of the two alternating-current sources in proportion to its share of the load. When an inverted converter operates singly, its speed may be seriously affected by a change in load or power-factor on the alternating-current side. A lagging alternating-current load will demagnetize the main fields and the converter speed will increase, as would that of any direct-current motor with weakened field.

**98. Alternating voltage control.** There is no means of varying the alternating voltage corresponding to the reactance and series-winding method used with the synchronous converter. The alternating voltage may be controlled by any of the other methods discussed in connection with the synchronous converter.

**99. Inverted converters are usually shunt-wound** in order to secure as nearly constant speed and frequency as possible.

**100. Correction for overspeeding.** Where inverted converters are subject to loads of varying power-factor and where constant speed is essential, it is customary to use a separately excited field winding, the excitation being

* See footnote, Par. 22.

Digitized by Google

supplied by a direct-connected exciter. The exciter is designed with an unsaturated magnetic circuit so that a change in speed will produce a maximum change in exciter voltage. With this arrangement an increase in speed of the inverted converter is at least partially corrected by the increase of its excitation due to increased exciter voltage.

101. **Protection against overspeeding.** Where the conditions do not require the separate exciter, it is customary to install an overspeed tripping device to protect the converter and its alternating-current load from excessive speed due to unusual conditions.

102. **Applications of the inverted converter.** The following applications of the inverted converter may be mentioned: (a) to supply a small amount of alternating-current from an existing direct-current supply; (b) to form a connecting link between alternating-current and direct-current systems for the transfer of energy in either direction. Under the latter condition the converter may operate either direct or inverted. An induction regulator or other means of varying the voltage is necessary to control the transfer of energy through the converter or, in the case of operating the load on one system entirely through the converter, to compensate for the voltage drop in the converter and transformers. (c) To enable a storage battery to be used to equalize the energy input in an alternating-current system. Here, also, a means of varying the voltage of the converter is necessary to control the charge and discharge of the battery. A notable installation of this kind is at the Indiana Steel Company, where a 2,000-kw. 250-volt, 25-cycle split-pole converter is used.

## MOTOR CONVERTERS

### BY F. D. NEWBURY, M.E.

103. **Structure.** The motor converter, or cascade converter, as it is sometimes called, consists of two elements, or machines, coupled together mechanically and electrically. The primary element, having the structure of an induction motor with a phase-wound rotor, performs the functions of a voltage, frequency and phase converter and of an induction motor. The secondary element, having the structure of a synchronous converter (with taps to the winding but without collector rings), performs the functions of a direct-current generator (driven by the induction motor, the rotors being mounted on the same shaft) and of a synchronous converter (receiving energy of suitable voltage, frequency and phase from the rotor winding of the primary element).*

104. **Starting resistance.** Three of the inside terminals of the rotor winding of the primary element are attached to collector-rings, to which the starting resistance is also connected. When operating at synchronous speed, all of the inside terminals of the rotor winding of the primary element are connected together to form the neutral.

105. **The rotor of the primary element is wound** with either 9 or 12 phases, the large number of phases being used to decrease the armature copper loss of the commutating machine. The large number of connections between the two rotors does not lead to any complication as they can be made solidly without collector-rings.

106. **Transformers are required only** when the line voltage exceeds the highest voltage for which the primary element can be safely and economically wound. In this respect the motor converter is on nearly equal footing with the synchronous motor-generator set. The difference in favor of the latter is due to the fact that the synchronous motor can be satisfactorily wound for higher voltages than the induction-motor element of the motor converter.

107. **Applications.** The motor converter occupies a position between the motor-generator set and the synchronous converter. Its main advantage over the motor-generator set lies in the fact that a part of the energy is transformed electrically and, therefore, more efficiently than in the motor-gener-

Digitized by Google

ator set in which all of the energy is transformed mechanically. For the same reason it is less efficient than the synchronous converter in which the entire output is transformed electrically. Its main advantage over the synchronous converter lies in the fact that the commutating machine of the motor converter operates at a frequency lower than the line frequency—usually at half the line frequency. This advantage applies only in the case of line frequencies above 40 cycles per sec. and for the higher direct-current voltages, and has been lessened even for these conditions by recent improvements in high-frequency synchronous converters. The motor converter has found its most extensive application in England and Germany. In England approximately 150,000 kw. of capacity has been installed since 1904, and in Germany approximately 65,000 kw. of capacity has been installed, mainly since 1908. These figures were compiled in July, 1913. Practically nothing has been done in the United States toward introducing the motor converter commercially, mainly due to the previous development of the high frequency synchronous converter.

**106. Equations of the motor converter.**

$$\text{Synchronous speed} = \frac{\text{Line frequency} \times 120}{\text{Sum of poles of both elements}} \quad \text{(r.p.m.)} \quad (4)$$

$$\text{Rotor frequency} = \text{Line frequency} - \left(\frac{\text{Primary poles}}{120}\right) \text{(r.p.m.)}$$

$$\text{(cycles per sec.)} \quad (5)$$

$$\text{Power transformed electrically} = \text{Total output} \left(\frac{\text{Secondary poles}}{\text{Total poles}}\right) \quad (6)$$

$$\text{Power transformed mechanically} = \text{Total output} \left(\frac{\text{Primary poles}}{\text{Total poles}}\right) \quad (7)$$

When the numbers of poles of both elements are equal, as is usually the case, these relations obviously become very simple.

**109. The average armature current and heating** in the commutating element is less than in a direct-current generator of equal rating, but more than in the corresponding synchronous converter. Assuming an equal number of poles in the two elements of a motor converter, the commutating element is operating half as a direct-current generator and half as a synchronous converter. Assuming further a twelve-phase rotor circuit and 100 per cent. power-factor at the terminals of the primary element, the average loss will be approximately 0.34 (relatively), the equivalent direct-current generator loss being unity. This is about 30 per cent. greater than the average loss in the ordinary six-phase synchronous converter, also at 100 per cent. power-factor. The maximum loss in one conductor is approximately 10 per cent. less than the maximum loss in the six-phase synchronous converter, at 100 per cent. power-factor.

**110. The armature loss** increases less rapidly with reduction in power-factor than in the 6-phase synchronous converter, due to the generator current loss, which does not vary with power-factor, and to the higher number of phases employed.

**111. Power-factor.** The power-factor at the line terminals of the primary element may be varied as in the simple synchronous converter by varying the field excitation of the commutating machine. The magnetizing current for the primary element may be taken from the line or from the secondary element as desired. This is controlled by the excitation of the commutating machine. If the set is operated at 100 per cent. power-factor, it follows that the secondary element is operating at a leading power-factor (with respect to line voltage) in the neighborhood of 93 per cent. at full-load. This has an important bearing on the heating and size of the commutating machine. See Par. 117.

**112. Voltage control.** A fixed voltage ratio exists between the alternating-current, and the direct-current sides of the commutating element of the motor converter, as in the synchronous converter, and the same means for varying the direct-current voltage must be employed. In a shunt-wound motor converter the direct-current voltage drops with the load assuming constant alternating voltage. In this case the necessarily high reactance of the primary element is a disadvantage. In a certain 500-kw.

Digitized by Google

motor converter the voltage dropped 5 per cent. between no load and full load. This is less than in a corresponding direct-current generator but more than in a corresponding synchronous converter. The motor converter is well adapted to voltage regulation by reactance and series-field excitation. In general, the primary element will contain inherently sufficient reactance to obtain a 10 per cent. voltage increase (assuming constant primary alternating voltage) with permissible range in power-factor. This range in voltage is ample for the ordinary railway system. Voltage ranges of 20 per cent. to 30 per cent. required by lighting systems using storage batteries cannot be obtained economically by reactance and series-field excitation. For such voltage variation an induction regulator, alternating-current booster or direct-current booster is required. The alternating-current synchronous booster must have the same number of poles as the secondary element and must be connected, electrically, between the primary and secondary rotor windings.

**113. Relative size and cost.** The cost of the primary or induction element will be approximately the same as that of an induction motor with phase-wound rotor at double the running speed (assuming equal primary and secondary poles). The cost of the secondary or commutating element will be less than that of a direct-current generator of the same rating and more than that of a synchronous converter of the same rating and operating frequency. The cost of the induction element will be somewhat more than that of stationary transformers necessarily used with the synchronous converter. On the basis of a line voltage so low that transformers are unnecessary with the motor converter, the cost without transformers is approximately the same as that of the higher-frequency synchronous converter and the necessary transformers. In case transformers must be used with either form of converter on account of high line voltage, the cost of the motor converter installation will be from 30 per cent. to 40 per cent. greater than the synchronous converter installation.

**114. Efficiency.** At capacities of 500 kw. and above, the efficiency of a synchronous converter and transformers would be 1.5 per cent. to 2 per cent. better than the motor converter without transformers, assuming American conditions which require the use of open armature slots in the primary element. Including the transformer in the motor converter installation would reduce its efficiency below that of the equivalent synchronous converter installation from 3 per cent. to 4 per cent.

**115. The method of starting** is the same as in an induction motor with phase-wound rotor, a three-phase resistance controller being used as indicated in the diagram in Fig. 22. It will be noted that, during starting, three phases of the rotor winding of the induction element are in series with the armature winding of the commutating element, the other phases remaining open at the neutral. After the main-line switch is closed, the rotor circuit of the induction element is closed through the starting resistance. As the rotor begins to revolve, two alternating currents are superimposed in the rotor circuits, one at maximum frequency decreasing with the speed, due to the induction element, and one at minimum frequency increasing with the speed, due to the commutating element. The latter current is appreciable only near synchronism or in the case of separate direct-current excitation of the secondary element. As the rotor approaches its normal running speed, these two currents approach the same frequency, which is indicated by a slow oscillation of the needle of the voltmeter connected in the starting circuit. At the moment the voltmeter needle passes through zero, the starting resistance is short-circuited and the set will thereafter operate synchronously. The neutral points of all the rotor phases are connected together and the starting brushes lifted from the rings by a mechanical device. By proper selection of the starting resistance, the starting current may be maintained at a low value throughout the entire starting operation. Due to the small armature current during starting, the direct-current voltage will always build up with the correct polarity. The field reversing switch commonly used with alternating-current self-starting synchronous converters is unnecessary.

**116. The motor converter may be used to supply a three-wire direct-current circuit** without change except that the brushes are left on the rings after starting. They are connected to the middle terminals of a

Digitized by Google

three-pole double-throw switch, one set of outside terminals being connected to the starting resistance and the other set being short-circuited and connected to the direct-current neutral lead.

**117. Commutating poles may be used on the commutating element** as in any synchronous converter. Due to the combined generator and converter action the ampere-turns required on the commutating poles more nearly approach the ampere-turns on the equivalent direct-current generator than on the equivalent synchronous converter.

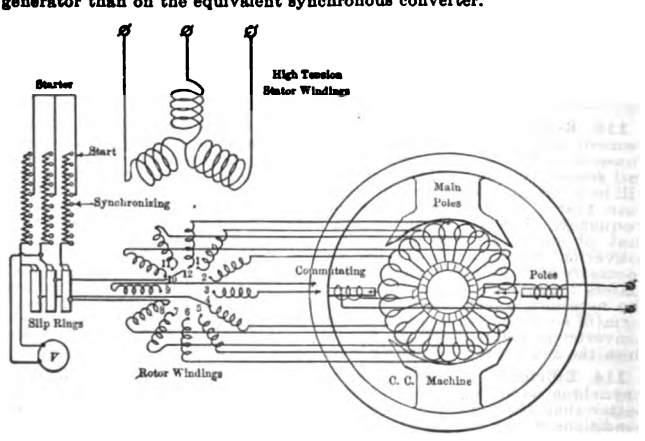

FIG. 22.—Diagram of connections of motor converter.

## DIRECT-CURRENT CONVERTERS

**BY ALEXANDER GRAY.** See p. 2

**118. Theory of operation.** A three-wire generator, operating with no current in one side of the system, may be used as a direct-current converter with a ratio of two to one. Such conditions of operation are shown diagrammatically in Fig. 23. If the armature be connected across the terminals *a* and *b*, it will rotate as a direct-current motor armature and will take a current $i_o$, at a voltage $2e$, to supply the no-load losses in the machine. If now two diametrically opposite points *c* and *d* be connected through a coil *C* of high reactance and negligible resistance, and if the middle point *f* of the coil be connected as shown in Fig. 23, the machine will become a three-wire generator (Sec. 8, Par. 193). The point *f* is then midway in potential between *c* and *d* and, since the e.m.f. between *c* and *d* is alternating, an alternating current, supplied from the mains, will flow in the reactance coil. This current will be small since the reactance is large.

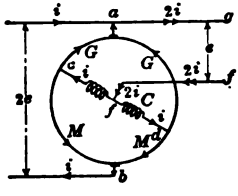

FIG. 23.—Current distribution in a direct-current converter.

A load current at voltage $e$ may now be drawn from terminals *f* and *g*, and the current distribution in the system will then be as shown in Fig. 23, the no-load currents being neglected. The currents in sections *M* flow against the generated e.m.f., so that these sections may be considered to act as motors; the currents in sections *G* flow in the direction of the generated e.m.f., and so these sections may be considered to act as generators. The driving torque due to the motor sections must overcome the retarding torque due to the generator sections.

Digitized by Google

**119. Armature currents.** The current in the armature conductors varies as the armature revolves; this may be seen from Fig. 24 where the armature is shown in four different positions.

In position *A*, the resistance from *c* to *a* is equal to that from *c* to *b*, and the current $i$, entering the armature at *c*, divides into two equal parts. In position *B*, the resistance from *c* to *a* is less than that from *c* to *b*, and the current $i_a$ is greater than the current $i_b$.

In position *C*, the current in *ca* is practically equal to $i$ and that in *cb* practically zero. In position *D*, the currents in all the conductors are zero.

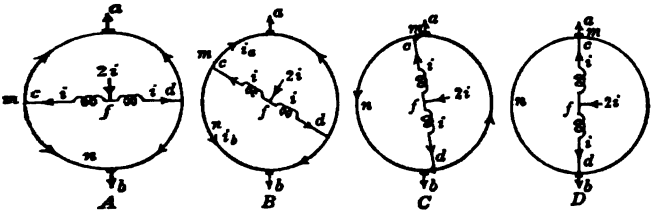

FIG. 24.—Relation between current and position of armature.

Fig. 25 shows approximately how the current varies in two coils *m* and *n* as the armature makes one revolution. In coil *m*, the current varies from zero to $i$ while in coil *n* it varies from $-\frac{1}{2}i$ to $+\frac{1}{2}i$; the armature coils are therefore not equally heated. Those next the leads *c* and *d* are the hottest and those midway between the leads are the coolest.

**120. The rating of a direct-current converter** depends upon the number of phases of the reactance coil. With a 2-phase reactance coil, as shown in Fig. 26, the maximum current in the conductors is less than $i$, and the current in each armature coil is more nearly constant than when only one reactance coil is used. For the same average armature copper loss in each

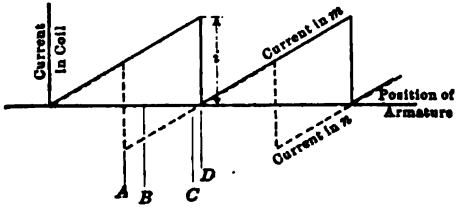

FIG. 25.—Variation of current in coils *m* and *n* during one revolution of armature.

case, a direct-current generator can be given the following ratings when used as a direct-current converter:*

1.00 as a direct-current generator;
1.22 as a direct-current converter with one reactance coil;
1.55 as a direct-current converter with two reactance coils;
1.64 as a direct-current converter with three reactance coils.

**The cost and weight** of the equivalent direct-current generator may be obtained from Fig. 67 (Par. 178) Sec. 8, an addition of 5 per cent. being made for the slip-rings.

**121. The secondary voltage of such a system cannot readily be controlled** independently of that of the primary; it decreases with increase of load according to Eq. 38 in Sec 8, Par. 194 and, with a reasonably priced

* Steinmetz, C. P. "Elements of Electrical Engineering," p. 337.

Digitized by Google

reactance coil, this decrease in voltage can hardly be less than 3 per cent. at full load.

**122. The rating of the necessary reactance coil** may be found from Sec. 8, Par. 197. The frequency, which equals the number of poles multiplied by the r.p.m. and divided by 120 will generally be between 15 and 40 cycles per sec.

**123. The Dettmar and Rothert split-pole machine** (Sec. 8, Par. 192) when used as a direct-current converter has the advantage that the secondary voltage can be controlled independently of that of the primary. Each pole of this machine is split so as to form two polar projections of like polarity and these are excited independently of one another. The neutral brush is placed on the commutator midway between the positive and the negative brushes and, by varying the excitation of one polar projection relative to that of the other, the flux entering the armature between the positive and the neutral brushes may be changed relative to that between the neutral and the

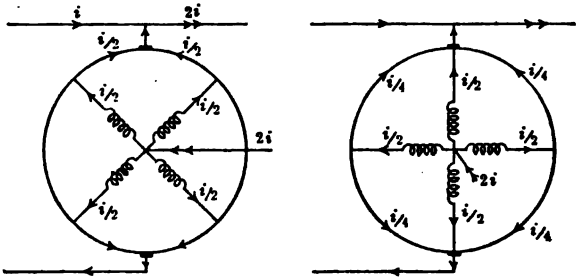

FIG. 26.—Current distribution in a direct-current converter with a two-phase reactance coil.

negative brushes, or the potential of the neutral brush may be varied as desired. By the use of suitable shunt and series coils on the polar projections, any desired degree of compounding may be obtained and, in the extreme case, a constant current may be obtained from the secondary of such a machine while the primary is operating at constant potential.

**124. The C. M. B. autoconverter** is another type of split-pole machine with the armature tapped by brushes placed between the main positive and negative brushes. A standard line of these machines is on the market and can be supplied with a transformation ratio as high as four to one, and with such a combination of shunt-field and series-field coils that a drooping secondary characteristic may be obtained if desired for constant-current operation. They are supplied with ball bearings and have an efficiency which varies from 75 per cent. for a 1 kw. unit to 86 per cent. for a 10 kw. and 94 per cent. for a 50 kw. unit.

**125. Applications.*** Direct-current converters of this latter type are used in place of motor-generator sets for many purposes, among others, to obtain 50 volts from a line of higher voltage for the operation of arc lamps at 50 volts in bioscope sets and search lamps. A constant-current characteristic is the most suitable for arc-lamp operation. They are also used for electric welding, the machines being built with such characteristics that, on short-circuit, the current is only 10 per cent. more than full-load current, while the voltage drops practically to zero.

# DYNAMOTORS

BY ALEXANDER GRAY

**126. General description.** The dynamotor is similar to the motor-generator set except that the two armature windings are on the same core and revolve in the same magnetic field, each winding being connected either to a commutator or to collector-rings, in accordance with its use for direct or for alternating current respectively. It is rarely necessary to change from direct current to alternating current, so that machines for such purpose are special. A change from alternating to direct current may be realized with less expense by the use of a rotary converter, with a transformer if necessary, than with a dynamotor.

**127. Armature reaction.** The armature for a direct current to direct-current type of dynamotor is shown diagrammatically in Fig. 27. Here the transformation ratio is four to one, so that there are four times as many effective turns in one winding as in the other. The direction of the generator current is that of the generated e.m.f., but the current in the motor winding is in the opposite direction. If the losses in the machine be neglected, then the

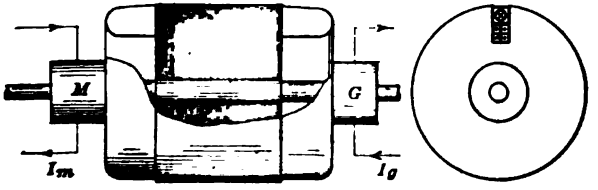

FIG. 27.—Arrangement of dynamotor armature and commutator.

motor input, $E_m I_m$ equals the generator output, $E_g I_g$, and the value of effective ampere-turns in the motor armature, $n_m I_m$ equals the value of effective ampere-turns in the generator armature, $n_g I_g$. Therefore the m.m.fs. of the two windings are equal and opposite and there is no resultant armature reaction. For this reason, the dynamotor can be allowed a smaller air gap, a smaller exciting current, and a lighter field coil than a standard machine built upon the same frame.

**128. The commutation** of these machines is exceedingly good if the brushes on the two commutators are so placed that the short-circuited coils of each of the two windings lie in the same slot. Under such conditions the currents in these coils change at the same time and in opposite directions, so that the reactance voltage is small (Sec. 8, Par. 43). Dynamotors can therefore have deep slots and low-resistance brushes and in consequence are suitable for delivering large currents at low voltages.*

**129. Voltage regulation.** The principal objection to the standard dynamotor is that the secondary voltage cannot be regulated without changing the excitation of the primary. The ratio of the terminal voltages is fixed by the ratio of effective armature turns and by the voltage drop due to the resistance of both armature windings, so that the terminal-voltage ratio is independent of the excitation and changes with the load. The transformation ratio for a given load can be changed only by inserting a resistance or a booster in the primary or the secondary circuit.

**130. Combined dynamotor and booster.** A machine which is equivalent to a combined dynamotor and booster can be made by extending one armature winding a longer distance axially along the core than the other, and applying to this extended part of the core a magnetic field from an auxiliary field system. The exciting current for this auxiliary field can be so regulated as to change the voltage of one winding independently of that of the other. If this field system be excited with series-field coils, the secondary voltage can be made to vary with the load, as desired. The chief advantage of this latter machine over the motor-generator set is that it requires less

* Sheldon and Hausmann. "Dynamo-electric Machinery," Vol. I, page 266.

Digitized by Google

floor space and will have a higher efficiency, but will probably not be cheaper if the machines are of corresponding construction.

**131. A special dynamotor is extensively used for telephone ringing.** The motor winding is for direct current and the other winding is connected to two slip-rings in order to deliver alternating current at from 16 to 19 cycles per sec., and about 75 volts (effective).

**132 Dynamotors can be used in place of motor-generator sets** only when the regulation of voltage is not of great importance as, for example, in the ringing of bells and gongs, the operation of signals in connection with fire alarms, telephone systems, annunciators and many other kinds of signaling, and the operation of magnetic contactor switches. For telegraphic work, dynamotors are often used in place of primary batteries, the secondary voltage being 50 to 500 volts direct current, depending on the length of the line (Sec. 21).

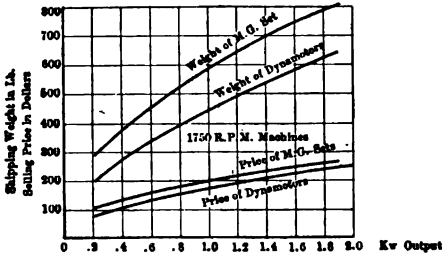

FIG. 28.—Weights and costs of small dynamotors and motor-generator sets.

**133. Cost of Dynamotors.** Since the two armature windings are upon the same core, that core will be larger for a dynamotor than for a generator of the same output. Fig. 28 shows the shipping weights and selling prices of small dynamotors and motor-generator sets of substantial make on a single bed plate, the motor-generator set consisting of two machines joined by a flexible coupling.

## DOUBLE-CURRENT GENERATORS

### BY F. D. NEWBURY, M.E.

**134. Armature currents in the double-current generator.** A machine having the same structure as the synchronous converter may be used to generate both alternating and direct current if driven by a suitable prime mover. Unlike the synchronous converter, the armature currents in the double-current generator are not less than in the corresponding direct-current generator. The alternating and direct-current are not subtractive, as shown in Figs. 1 and 2, but are additive, since both are generator currents. For the same reason, the generation of both alternating and direct current in the same armature winding is not favorable to commutation as in the synchronous converter, but is detrimental.

**135. Dependance of direct-current voltage on alternating voltage.** A double-current generator has none of the advantages of the synchronous converter and has many disadvantages of its own. One of the most serious disadvantages is the dependence of the direct-current voltage on the alternating voltage and on variations in alternating-current load and power-factor. A change in alternating-current load or power-factor will cause a change in the magnetizing effect of the alternating current in the armature winding and thus change the resultant magnetization on which the direct and alternating voltages depend. To assist in maintaining steady direct-current voltage, it is customary to excite double-current generators separately.

Digitized by Google

**126. Alternating-current parallel operation.** If double-current generators are operating in parallel with a relatively large alternating-current system on which the alternating voltage is held constant, the direct-current voltage will also be constant and cannot be varied independently of the constant alternating voltage.

**127. Limitations of design.** From the design standpoint, the double-current generator is handicapped by the rigid relationship between poles and speed required by the frequency. This, in general, results in the use of many more poles than would be employed in an equivalent direct-current generator, causing an appreciable increase in cost. This is particularly true with slow engine speeds and high frequency. It is also impossible to use commutating poles on account of the effect of variation in alternating-current load and power-factor. No machines larger than 2,500 kw. have ever been built in this type.

**128. Abandonment of slow-speed type.** During the past 10 years, no slow-speed engine-driven double-current generators of any importance have been installed. The reasons for this have been the disadvantages of the double-current generator already enumerated and the lower cost and greater flexibility of alternating-current generators used in conjunction with synchronous converters.

## STEAM POWER PLANTS

BY REGINALD J. S. PIGOTT

### LAWS OF HEAT TRANSFER

**1. No heat can be transmitted from a cold body to a hotter one** flue gases must, therefore, leave the boiler at not less than the steam tempera ture in an ordinary boiler, or at not less than the incoming feed-wate temperature in the counter-current type of boiler.

**2. Two kinds of heat transfer** take place in a boiler; absorption by radiation from incandescent fuel direct to heating surface, and heat transmission by contact and convection. Stefan and Boltzmann's law states that absorption by radiation is proportional to difference of the fourth powers of the two temperatures involved.

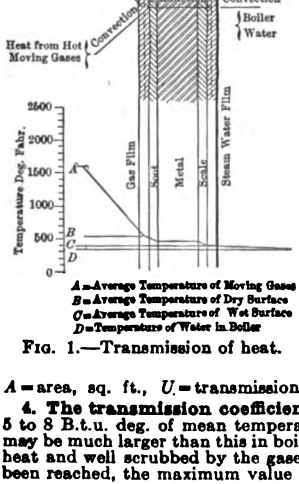

FIG. 1.—Transmission of heat.

B.t.u. radiated per sq. ft. per hour = $16 \times 10^{-10} (T_1^4 - T_2^4)$ (1)

where $T_1$ = absolute temp. in deg. Fahr. of "black" incandescent body, and $T_2$ = absolute temp. in deg. Fahr. of receiving body.

A "black" body such as carbon, in any form except the crystalline, will absorb all heat transmitted, reflecting none. Metal and other materials will reflect from one-fourth to one-half of that received.

**3. Heating by convection** from hot gases to water is proportional to some power of each of the velocities of the moving gases and water or steam. The heating is also proportional to the density of the fluids and to the absolute temperatures, since these influence the molecular energy. The formula for heat transfer by convection is,

$$H = A\,U(T_1 - T_2) \qquad (2)$$

where $H$ = B.t.u. transmitted per hr., $A$ = area, sq. ft., $U$ = transmission coefficient, $T_1 - T_2$ = mean temp. diff.

**4. The transmission coefficient** for normal rating is somewhere around 5 to 8 B.t.u. deg. of mean temperature difference, per sq. ft., per hour, but may be much larger than this in boilers with much surface exposed to radiant heat and well scrubbed by the gases. The upper limit has probably never been reached, the maximum value for recorded tests being about 20.

**5. Effect of dirty surfaces.** One important difference noticeable between absorption of heat by conduction and by radiation is that the relative cleanness of the surface affects the rate of conduction very readily, but absorption of heat by radiation is practically unaffected. Soot increases the thickness of the film of motionless gas, besides adding its own resistance to heat flow.

**6. The resistance of the film of inert gas** entangled in the rough surface of the tube (or soot) is from 20,000 to 35,000 times as great as that of the metal tube alone, so that the thickness of the dead gas film is the controlling

factor. In absorption of heat by radiation, however, the interposition of a gas film or layer of soot has practically no effect, since conduction does not bear a part in the action.

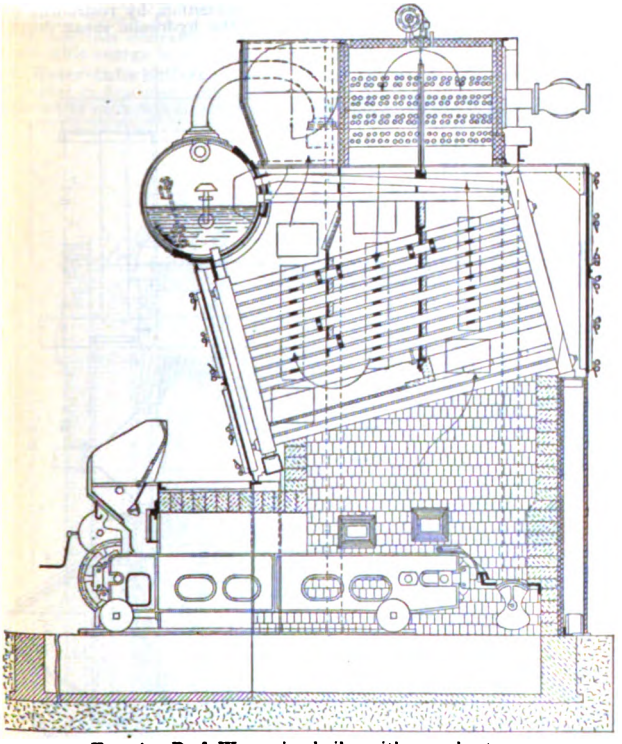

FIG. 4.—B. & W. marine boiler with superheater.

## BOILERS

7. **Boiler types**: in the following classification modern types only are considered.

- **Fire Tube...**
  - Horisontal return tubular (Fig. 2).
  - Scotch (Fig. 3).
  - Continental and other internally fired types (Fig. 3).
- **Water Tube.**
  - Definite circulation path.
    - B. & W..... (Rust; Stationary (Fig. 5).; Marine (Fig. 4).)
    - Heine, etc., etc., and 7 (Stirling (Fig. 6).)
    - Yarrow
    - Thorneycroft.
  - Field Tubes..... Niclausse

Digitized by Google

All types give efficiencies not differing widely when subjected to the same kind of furnace and flame conditions, the structure having almost no inherent influence upon efficiency. But inasmuch as the structure may influence very materially the conditions of combustion, by restricting combustion spaces, by altering the length and the hydraulic mean depth of

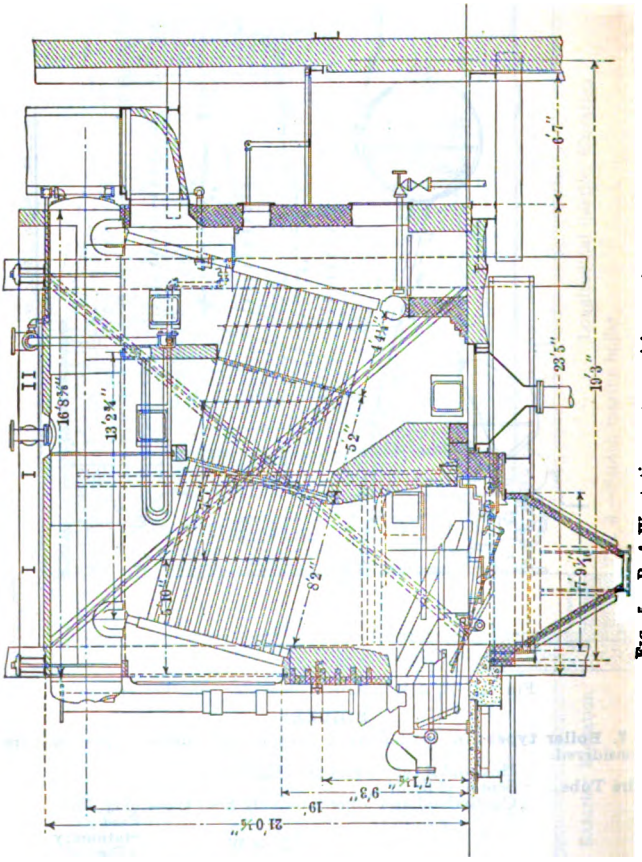

FIG. 5.—B. & W. stationary type with superheater.

gas passages, and by extinction of flame and accumulation of dirt, it may alter the efficiencies somewhat. If combustion could be entirely complete, so that the flame would be extinct before reaching any heating surface, it would make no difference what type of boiler were employed so far as efficiency is concerned.

Digitized by Google

8. **Fire-tube boilers** are cheapest in first cost, but lowest in capacity for space occupied; in general they are the most difficult to keep in good operating condition, especially with dirty water, since the water space is not accessible. The internally fired boilers such as the Scotch and the Continental (or similar) types are somewhat superior in capacity, but not up to the water-tube type. As a class, fire-tube boilers, from the standpoint of safety, are least desirable, as they carry a large body of hot water, storing considerable energy to be liberated at the instant of rupture.

9. **Water-tube boilers** are much lighter and smaller per unit of capacity, and higher in first cost than tubular boilers, but easier to maintain inasmuch as the water surface is all practically accessible, either for hand cleaning or for

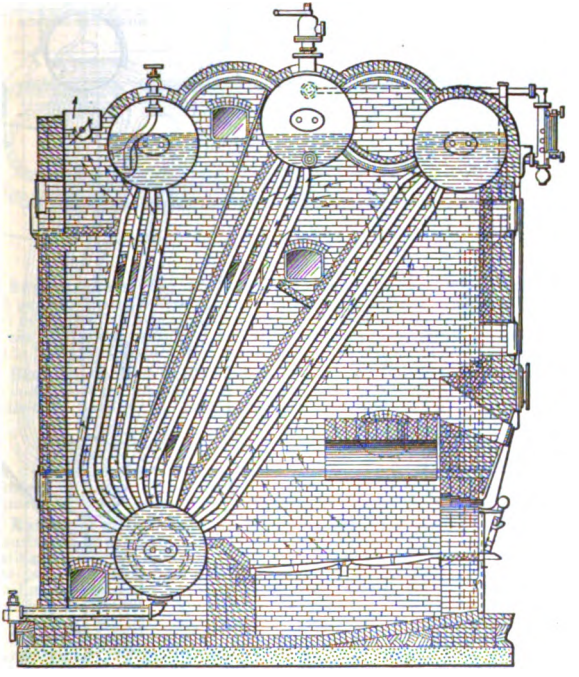

FIG. 6.—Stirling boiler.

turbine tube cleaners. They are very safe, having very small water storage (subdivided into many smaller bodies by the tubes), and are made up almost entirely of the strongest natural shapes—cylindrical—with little or no stayed surface. There are practically no records of serious accidents resulting from the explosion of water-tube boilers.

10. **Field-tube boilers** are almost unused except for the French marine boiler known as the Niclausse. The principal objection to their use is the uncertain and spasmodic nature of the circulation which may partake of the nature of flash generation, alternating with periods of flooding with water, causing strains due to rapid and unequal expansion and contraction.

Digitized by Google

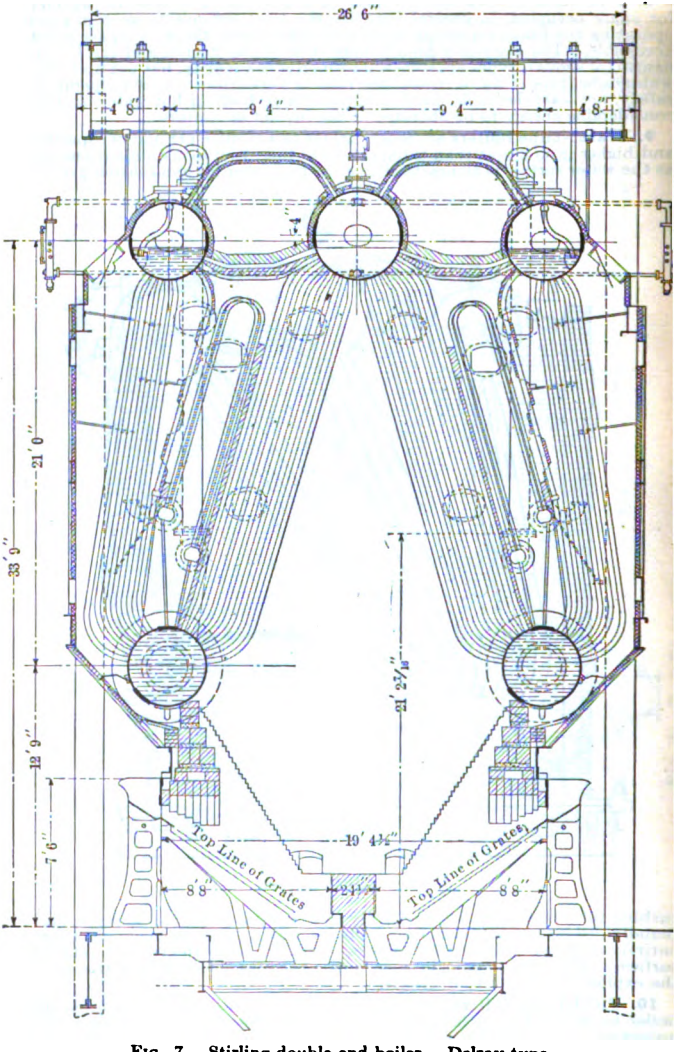

Fig. 7.—Stirling double-end boiler. Delray type.

Digitized by Google

**11. Flash generators** are at present unused except for steam automobile boilers and some torpedo boats. In American power stations they are unknown. However, if any standard boiler, such as the B. & W. or Stirling, be forced much above its normal rated capacity, the generation, in the lower rows of tubes at least, becomes of the flash type by reason of the extreme conditions.

**12. Superheaters** are of two general types: self-contained, and separately fired. The separately fired superheater is unpopular in America, chiefly because it has not shown such pronounced economies as the self-contained type. The two types of self-contained superheater are the plain tube and the protected tube types. To the former class belong the Heine, the B. & W. (Fig. 5) and the Stirling; to the latter class belong the Foster (Fig. 8) and the Schwörer.

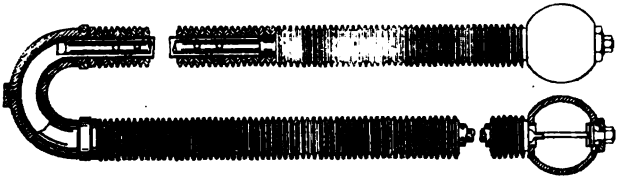

FIG. 8.—Foster superheater.

**13. Superheaters may be located** (usually) between the first and the second passes, or in the breeching. With later boilers of the ordinary stationary types the first position is popular. With the marine types now sometimes used in power stations, the latter position is satisfactory, as the gases leave the boiler at a higher temperature (see Marine B. & W. boiler, Fig. 4).

**14. Heating surface is defined as** any surface in a boiler or superheater which is exposed to hot gases on one side and water or steam on the other. In water-tube boilers the heating surface is defined as

$$\frac{\pi dln}{12} + \frac{\pi DLN}{24} \qquad \text{(sq. ft.)} \qquad (3)$$

where d = outside diameter of tubes in in. l = length of tubes in ft., n = number of tubes, D = outside diameter of drums in in. L = length of drums in ft. and N = number of drums, headers not included.

**15. Rating of superheaters.** Superheaters are not usually rated by sq. ft. of surface, but are figured for each case. A good average rule is 15 sq. ft. of heating surface per boiler h.p., for unprotected tubes; 18 sq. ft. of heating surface per boiler h.p., for protected tubes. The reason for using larger figures for superheaters than for steam-making surface is that heat transmission is much more difficult between gas, iron and gas, than between gas, iron and water, or between gas, iron and vapor, the latter two conditions obtaining in the boiler proper. The protected tubes interpose an additional resistance to heat transfer because of the cast-iron protection rings, the roughness of which also materially increases the thickness of the dead gas film.

**16. Grate surface** is any surface upon which coal is being burned. In hand-fired furnaces this amounts to the horizontal dimensions of the furnace, side wall to side wall, and front wall to bridge. With the automatic stoker, the term becomes more or less anomalous, since part of the surface may be used exclusively for coking, and the grates may not be horizontal; and part of the grates may be used only for accumulating clinker and ash. With underfeed stokers, coal is not burned upon the grates to any appreciable extent. The term is useful for comparison, if the projected area of the furnace is used in each case.

**17. The ratio of heating surface to grate surface** was once considered important and was generally made 60 to 1 when good coals were used, but now not much attention is given it. This ratio shows a tendency to decrease to 30 to 1 or 40 to 1 recent installations, particularly with stokers intended

Digitized by Google

for forcing to high capacities, or where low-grade fuel such as culm, or No. 3 buckwheat is burned.

**18. The value of the boiler h.p.** is at present 34.5 lb. of water evaporated from and at 212 deg. Fahr., per hour; this is equivalent to 33,479 B.t.u. per hour. A new unit recently proposed to eliminate this somewhat illogical unit, is the **myriawatt**,* a multiple of the watt, having a value of 34,150 B.t.u. per hour, about 2 per cent. larger than the boiler h.p.

**19. Evaporation.** Taking dry coal, the actual evaporation per lb. is,

$$E = \frac{W}{w} \tag{4}$$

$$E' = EF \tag{5}$$

$$F = \frac{H - h}{970.4} \tag{6}$$

$E$ = actual evaporation
$E'$ = equivalent evaporation
$F$ = factor of evaporation
$H$ = total heat of steam at boiler pressure and quality.
$h$ = heat in the feed water = feed temperature − 32.
$W$ = lb. steam per hr.
$w$ = lb. dry coal per hr.

970.4 = latent heat at atmospheric pressure = heat to convert 1 lb. of water to steam, from and at 212 deg. Fahr.

Or the above evaporation may be used "per lb. of combustible," substituting lb. of combustible per hour in place of lb. of dry coal per hour. All temperatures are expressed in deg. Fahr., and all pressures in lb. per sq. in., and all heat in B.t.u.

**20. Losses in boilers** comprise: (a) sensible heat escaping in flue gases; (b) sensible heat lost in hot ashes; (c) radiation of heat to external air from boiler setting; (d) incomplete combustion; (e) excess air. Theoretically some of these losses are avoidable. Actually, about the following proportions hold good in recent practice.

| | |
|---|---|
| Heat in coal | 100 per cent. |
| Heat absorbed in steam (overall efficiency) | 70 to 76 per cent. |
| Stack loss, sensible heat only | 10 to 15 per cent. |
| Incomplete combustion | 5 to 10 per cent. |
| Hot ashes | Negligible |
| Radiation and leakage | 6 to 8 per cent. |

**21. The combustion efficiency of automatic stokers** runs as high as 96 to 97 per cent. and is maintained up to a very high rating in some cases. That of a hand fire is seldom over 90 to 92 per cent. and generally much less. due to inevitable carelessness in operation.

**22. Radiation** is kept down by thorough lagging of exposed parts and by the usual double-walled construction of boiler settings (Figs. 5 and 6). It does not vary greatly for any type of boiler, but is reduced somewhat by setting in batteries instead of singly.

**23. Excess air** is caused by the slight vacuum in the setting due to draft: it can be reduced by painting or white-washing the setting and stopping up all cracks between metal and brick with plastic asbestos. In some cases enamel brick or sheet-iron settings are used, but the expense is not generally justified from this point of view alone. Another method of reducing **setting infiltration** is by the use of balanced-draft systems; in these the methods of forced draft, and natural or induced draft are so employed as to give practically zero pressure in the fire-box, by this means reducing the average difference of pressure from atmosphere, over the whole setting.

**24. Furnace efficiency** is expressed by the formula

$$\text{Furnace efficiency} = \frac{\text{Combustible burned}}{\text{Combustible fired}} \tag{7}$$

$$\text{Combustible burned} = (\text{Combustible fired}) - (\text{Combustible in ash}) - (\text{Combustible in unburned gas}) - (\text{Combustible in soot}). \tag{8}$$

* Stott and O'Neill. p. 411, *Trans.* A. I. E. E., Vol. 32, 1913.

Digitized by Google

Combustible fired = (lbs. dry coal) × (B.t.u. per lb. [by calorimeter]) (9)

Combustible burned = (combustible fired) − (B.t.u. per lb. of ash) × (lbs. ash) − (B.t.u. per lb. of soot) × (lb. of soot) − (B.t.u. in unburned gases). (10)

The last item is derived from the flue-gas analysis and as it always involves several assumptions, its accuracy is not very certain.

**25. Boiler efficiencies.** Fig. 9 gives a series of efficiency curves for various sizes and makes of standard boilers in central station service. The actual results in operation usually fall from 3 to 5 per cent. below test figures, the smallest falling off being noticed in those stokers which require the least hand manipulation during operation.

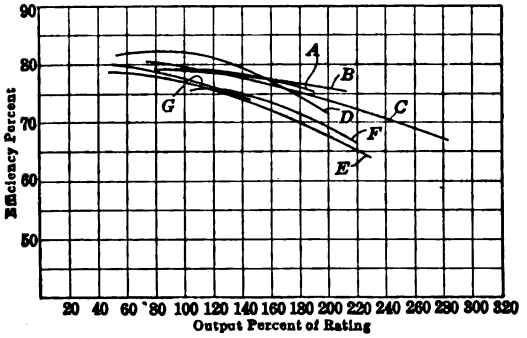

FIG. 9.—Boiler efficiency.

Combined efficiency, boiler and furnace: *A*, 2,365 h.p. boiler, Taylor stoker D. E. Stirling; *B*, 2,365 h.p. boiler, Roney stoker D. E. Stirling; *C*, 520 h.p. boiler, Taylor stoker B. & W.; *D*, 750 h.p. boiler, Taylor stoker B. & W. (part 2-in. tubes); *E*, 600 h.p. boiler, Green chain grate, B. & W.; *F*, 520 h.p. boiler, Westinghouse-Roney stoker B. & W.; *G*, 1,000 h.p. boiler, Taylor stoker B. & W.

**26. Combined furnace and boiler efficiencies.** The table below gives the pounds of water evaporated per pound of coal, and the pounds of coal required per boiler h.p. hr. with coals of various heat content and with boiler installations having varying combined boiler and furnace efficiencies.

| B.t.u. per lb. dry coal | 50 % | | 60 % | | 70 % | | 80 % | |
|---|---|---|---|---|---|---|---|---|
| | Evaporation per lb. coal | Lb. Coal per boiler h.p. hr. | Evaporation per lb. Coal | Lb. coal per boiler h.p. hr. | Evaporation per lb. coal | Lb. coal per boiler h.p. gr. | Evaporation per lb. coal | Lb. coal per boiler h.p. hr. |
| 8,000 | 4.142 | 8.33 | 4.971 | 6.94 | 5.799 | 5.96 | 6.627 | 5.20 |
| 9,000 | 4.660 | 7.41 | 5.592 | 6.18 | 6.524 | 5.28 | 7.456 | 4.63 |
| 10,000 | 5.224 | 6.60 | 6.269 | 5.50 | 7.314 | 4.72 | 8.359 | 4.13 |
| 11,000 | 5.695 | 6.06 | 6.834 | 5.05 | 7.973 | 4.33 | 9.113 | 3.79 |
| 12,000 | 6.213 | 5.56 | 7.456 | 4.63 | 8.698 | 3.97 | 9.941 | 3.47 |
| 13,000 | 6.731 | 5.12 | 8.077 | 4.27 | 9.423 | 3.66 | 10.769 | 3.20 |
| 14,000 | 7.249 | 4.76 | 8.698 | 3.97 | 10.148 | 3.40 | 11.598 | 2.98 |
| 14,500 | 7.508 | 4.60 | 9.009 | 3.83 | 10.511 | 3.28 | 12.012 | 2.87 |

Digitized by Google

Efficiencies at head of columns are combined boiler and furnace efficiencies. Evaporation is given in pounds of water "from and at" 212 deg. Fahr. per lb. of dry coal. The heating value can also be taken for coal "as fired" whence the "evaporation per lb. of coal" and the "pounds coal per boiler h.p. hr." will also be referred to coal "as fired." This latter use of the table will contain a slight error due to the absorption of a portion of the heat by the moisture in the coal.

**27. The failure of a furnace to burn all of the combustible** is due to two principal causes: (a) molecules of oxygen are not brought into contact with all the particles of combustible material; (b) the temperature may be too low for ignition when they are in contact. The first condition is found where some of the fixed carbon in the lumps of coal becomes surrounded by a coating of fused ash, so that the air never reaches it during the time that the lump is upon the grate. Another cause, in the case of bituminous coal, is the lack of proper mixture of the volatile matter with air. The second condition is found as a result of the first, if streams of stratified hot combustible gas and air leaving the furnace are brought into contact with the comparatively cold heating surface, they will quickly be chilled below the ignition point, and will sweep through the boiler without further combustion taking place.

**28. Water-tube boilers are generally rated** on one boiler h.p. for each 10 sq. ft. of heat surface; **Scotch marine types** on 8 sq. ft., and **horizontal return-tubulars** on 12 sq. ft. **Superheater surface** is usually based on a transmission coefficient of 5 to 8 B.t.u. per deg. of mean temp. difference per sq. ft., per hour.

An empirical formula given by Bell (Trans. A. S. M. E., May, 1907) is, Sq. ft. superheating surf. per boiler h.p. =

$$S_s = \frac{10T_s}{2(T_g - T_o) - T_s} \tag{11}$$

The temperature of gases at the superheater may be found from the following relations:

$S_s$ = superheater surface per b.h.p., sq. ft.
$S_a$ = per cent. of total surface passed over by gases before reaching superheater.
$T_s$ = superheat, deg. Fahr.
$T_o$ = saturated steam temp., deg. Fahr.
$T_g$ = temp. of gases at superheater, deg. Fahr.

$$(0.172S_a + 0.294)(T_g - T_o)^{0.16} = 1 \tag{12}$$

These two formulæ are based on the following assumptions: constant coefficient of heat transmission; furnace temperature 2,500 deg. Fahr.; flue temperature 500 deg Fahr.; steam pressure 175 lb. gage; one boiler h.p. equivalent to 10 sq. ft. of heating surface.

**29. Boiler design.** Since the efficiency of boilers is so little influenced by the disposition of heating surface, comparatively little original designing can or should be done outside of standard forms. For central-station work, the water-tube boiler has practically the whole field, the specifications for a boiler therefore look more to the safety and reliability, by rigorous attention to materials, than to the actual detailed design. The management of the furnace and combustion have much more to do with the efficiency of a boiler, than the arrangement of heating surface.

**30. Boiler settings** have become more or less uniform in general type. For the water-tube boilers, a steel structure or skeleton for supporting the boiler proper, the brick walls being merely self supporting, is now usual practice. Common red brick is used for the outer walls, a double-wall construction being employed to allow for the differential expansion of inner and outer surfaces (on account of the great temperature difference), to minimize radiation by interposing dead air space, and to reduce air filtration. Wherever the temperature exceeds 1,000 deg. Fahr., fire-brick is employed for this inner lining.

**31. The baffles** are always of fire-brick, of various special shapes, sometimes backed or supported on the cooler side by cast-iron bars or plates. Figs. 5 and 6 show these constructions.

Digitized by Google

**32. The setting for tubular boilers,** generally supports the boiler; for internally fired boilers, no setting is required (see Figs. 2 and 3).

**33. The computation of superheater surface** is much complicated by the change of temperature of the flue gases at the superheater with load on the boiler, and the uncertainty of the transmission coefficient. The amount of superheater surface installed for superheats of 100 deg. to 175 deg. Fahr. varies from 13 to 20 per cent. of the boiler heating surface. Fig. 10 gives results of actual tests.

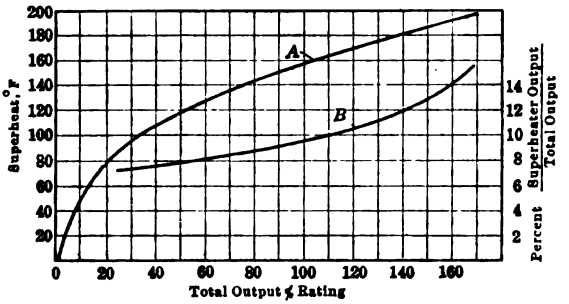

FIG. 10.—Superheater variation with output.

**34. Uptakes** are usually allowed 0.03 to 0.04 sq. ft. of cross-section (flue area) per rated h.p. of boilers attached. Where the uptakes are very long this allowance should be increased, or the loss of draft will be excessive. Where economisers are employed, the flues are best made of brick and combined with the economiser setting. Otherwise sheet-steel ducts, lagged with asbestos or other insulating material, are cheaper and more convenient. In nearly all cases the uptakes proper are made of steel. It is not necessary to line these with fire-brick unless the flue temperatures exceed 700 deg. a large part of the time; with properly operated boilers this condition need not occur. Bends in uptakes should be avoided, if possible, but where necessary should be of large radius; sudden changes of section should also be avoided.

**35. Flue areas** are based on a normal velocity of 25 to 40 ft. per second; maximum velocity, 60 to 70 ft. per second. The breeching area of water-tube boilers is about 0.03 to 0.045 sq. ft. per rated boiler h.p. It is best to be generous with areas wherever possible so as to keep the draft loss low.

**36. Safety valves** of the **pop type** are now always used, the weighted-lever type being prohibited by law in most cases. There are two principal classes: **low lift,** in which the rise of the valve is from 0.04 in. to 0.08 in.; and **high lift,** in which the rise is 0.12 in. to 0.16 in. The high-lift valves have been much more widely used in the last few years. Their principal advantage is greater relieving capacity; their principal disadvantage is possible slamming of the valves and destruction of the seat thereby; and, with dirty or hard boiler water, violent priming and throwing of water from the valve.

**37. The rule of the U. S. Board of Supervising Inspectors of Steam Vessels in regard to safety valves** is expressed as follows:

$$A = 0.2074 \left(\frac{W}{P}\right) \qquad (13)$$

where $A$ = safety-valve disc area, in sq. in., per sq. ft. of grate area under boiler,

$W$ = evaporation, in lb. of steam per hr. per sq. ft. of grate surface, and

$P$ = absolute pressure, in lb. per sq. in. at boiler.

This is based on an assumed ratio of lift to diameter of valve of $\frac{1}{24}$ and a 45 deg. bevel seat.

Digitized by Google

**38. Connection of safety valves.** There must be **no valves between the safety valve and the boiler connection**; seats and valve discs must be of such material as will not rust together; no valves are allowed in the discharge from safety valves; in fact it is preferable to have only a muffler on the valve, and no discharge pipe at all.

**39. Gage glasses** of the ordinary type should be connected, preferably, directly to the steam drum and protected by wire gauze if near the level where firemen or others are working. The Klinger type of gage glass with heavy corrugated plate glass and brass casing is much safer, but more costly; the water level is much more clearly distinguished.

**40. Quick-closing gage cocks** operated by chain or rod are now almost universally used. The gage glass and blow-off cocks should never be so arranged that the fireman must stand close to the gage glass when "blowing down."

**41. Manholes** provided for entry to boiler drums, preferably in the heads where they least affect the strength, are made of pressed plate steel and fitted from the inside of the drum against a bumped lip or saddle in the drum by means of one or two bolts made fast to a dog spanning the opening on the outside. The pressure inside the boiler keeps the manhole tight, the bolts being used only to pull the cover to a seat. The **gasket** between manhole cover and seat is of asbestos, lead alloy or corrugated copper. The standard dimensions are 11 in. $\times$ 15 in.

**42. Handholes** are placed in mud-drums, headers, etc., which are too small to admit the body, but must be cleaned and inspected. They are made in the same manner as manholes, but the dimensions are usually 4 in. by 6 in. or 6 in. by 8 in.

**43. The blow-off** should be connected to the lowest and quietest place in the boiler, where the mud and scale settle, or from specially designed chambers in which the sediment is induced to collect. The blow-off pipe must be protected from the fire, as it has normally no circulation of water to protect it. Many installations have been made with a plug cock next the boiler, followed by a gate valve to prevent leakage. There are now, however, one or two successful valves on the market which do not require the additional gate valve.

**44. The feed pipe** should enter the boiler so that the flow is in the direction of natural circulation in the boiler. Outside the drums the feed pipes are generally of brass to eliminate the chance of a break at this point from corrosion. A **check valve** is fitted at the entrance to each drum, to prevent water flowing back.

**45. The steam gage** is connected to the steam space of the boiler, to prevent blocking of the pipe by scale or mud. A **condensing coil** should be applied to prevent hot water or steam from getting into the Bourdon tube of the gage. **Thermometers** are practically never used as a measurement of steam pressure, except on tests, but are much more reliable.

**46. Pyrometers** are used for measurement of flue gas temperature, leaving the boiler, and are very valuable aids in checking the operation and efficiency.

**47. Safety plugs** are made of pure Banca tin, and are so placed that the active fire will play upon them, or at least in the first pass through the tubes. They are placed about 10 or 12 in. above the danger limit of low water; they are ordinarily protected by the water, but melt in case the level falls below them. The fire side of the plug must be kept clean of soot, or it may become so protected as to be inoperative.

**48. Boiler corrosion** is caused either by direct oxidation of the iron by **oxygen** dissolved in the water or by reaction with some **acids** present in the feed-water, having their source either in national acidity or from the products of decomposition of impurities introduced into the feed. Corrosion by oxidation is the more important, as the other is always avoidable by proper purification of feed water. Oxidation goes on continuously wherever dissolved air is present, and is much increased by the vibration or flexure of any particular point. The constant bending breaks off the film of iron oxides formed by the process, and exposes new surface to be attacked; for this reason pitting is commonest near joints where the flexure of some one portion of a plate is apt to be severe.

Digitized by Google

**49. Incrustation** is caused by the deposit of solid matter during the heating and boiling of the water. It may be merely a mechanically entrained impurity, such as mud and sand, or it may be the result of precipitation of various salts insoluble in hot water, or by super-saturation. The salts of magnesia, lime and iron are those giving most trouble in boiler water. Some of these salts are soluble and cause the formation of scale by super-saturation; others are insoluble in hot water and precipitate as the water is heated.

**50. Treatment of feed water.** The principal salts are iron, calcium and magnesium carbonate, bicarbonates, and sulphates. The bicarbonates are usually decomposed by boiling. The general method of treatment is by adding lime (CaO), and sodium carbonate ($Na_2CO_3$) called in the impure commercial form, soda ash.

**51. Removing the precipitation.** Where the character of the water or the plant layout does not allow the treatment in a separate purifying system, these reagents are added in the boiler feed, and the precipitation takes place in the boiler, assisted by the heat. The main object in this case is to precipitate the salts as soft scale, or mud, in order that it may be readily blown out. Periodic cleaning with some kind of mechanical cleaner is necessary, however, even with feed-water treatment, as some of the hard salts are bound to stick, especially in the hardest worked tubes over the hottest fires.

**52. Periodic inspection of boilers** is in itself a good preventive of accident. The straight tube, water-tube boilers lend themselves most readily to thorough inspection, as every part can be seen, and the whole of the shells can be hammer tested.

**53. Boiler insurance** covers the possible damage done by boiler explosion. The boiler insurance companies exercise a vigorous and valuable control over the manner of operation of boilers, and by their frequent enforced inspection, prevent little flaws from becoming disastrous weaknesses.

**54. Cleaning.** Those operations which make for safety in the boiler generally aid efficiency. A good rule is never to allow more than $\frac{1}{16}$ in. thickness of scale to collect; and to overhaul thoroughly every part of the boiler twice a year. In a well-operated plant, with moderately good water, this generally means cleaning the two rows of tubes nearest the fire about once a month, and the remainder of the boiler, twice annually. It generally pays, both in safety and efficiency, not to use water requiring more frequent cleaning of the boiler than last stated, but instead to purify the water in separate apparatus.

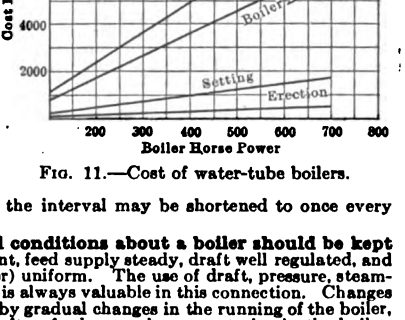

FIG. 11.—Cost of water-tube boilers.

**55. The removal of soot from the outside of the tubes** is usually required once or twice a week in well-operated plants; but for high rates of forcing, and especialy for low-grade fuels requiring heavy blast, the interval may be shortened to once every alternate day.

**56. As far as possible, all conditions about a boiler should be kept uniform**—water level constant, feed supply steady, draft well regulated, and firing (either by hand or stoker) uniform. The use of draft, pressure, steam-flow indicators or feed meters, is always valuable in this connection. Changes of load should be anticipated by gradual changes in the running of the boiler, since sudden alterations of draft or feed not only cause strains in the boiler, but loss of efficiency, thus disturbing the normal operation of the fire and flow of steam.

**57. Boiler costs.** Fig. 11 shows the variation in total cost of **water-tube boilers** of the B. & W. or Stirling types. The cost remains practically con-

Digitized by Google

stant at $12.00 to $12.40 per h.p. This is partly due to the fact that most of the smaller boilers are built for lower pressures than the larger units. If all were built for high pressures, say 200 lb. gage, the cost would follow approximately the rule given by C. H. Benjamin in 1902, which is.

$$\text{Cost in dollars} = 500 + 9.2 \text{ (rated h.p.), for boiler alone.} \quad (14)$$

**58. The average setting cost** for 300-h.p. to 600-h.p. units is $2.50 per h.p., and varies little. The delivered price is approximately 71 per cent. the erection cost 9 per cent., and the setting 20 per cent. of the total cost, which remains very nearly constant at about $12.40 per h.p. for horisontal water-tube boilers between 300 h.p. and 750 h.p. Gebhardt gives $1.00 per sq. ft. of heat surface as the price (delivered only), on all boilers over 100 h.p.

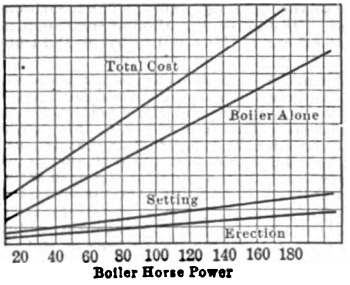

FIG. 12.—Cost of fire-tube boilers.

**59. The cost of vertical water-tube boilers** averages 10 per cent. less than horisontal water-tube boilers. Benjamin gives the cost in dollars = 500 + 8.5 × (rated h.p.), for vertical water-tube boilers (delivered only).

**60. The corresponding costs of fire-tube boilers** are given in Fig. 12.

## FURNACES AND STOKERS

**61. Principles of combustion:** Referring to Fig. 13, a stream of oxygen is shown ascending past a piece of white-hot carbon—say a piece of **coke**, or a piece of **anthracite** having practically no volatile matter. Provided the temperature of the coke is high enough, combustion takes place to $CO_2$ and CO, the former predominating. Now suppose this stream of CO and $CO_2$ flows past more incandescent coke with little or no oxygen in the immediate neighborhood. Some of the $CO_2$ will combine with the incandescent C and reduce to CO. This combustible gas now flows on till it finds more oxygen, and is then burned to $CO_2$. This oxidation and reduction may go on reversing many times during the travel of the stream through the bed of coal to the top of the fire, and the burning of CO to $CO_2$ by contact with the needed oxygen is evidenced by the familiar blue flame of anthracite coal fires.

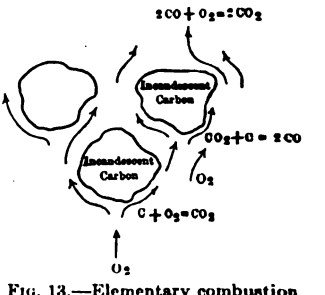

FIG. 13.—Elementary combustion of fixed carbon.

**62. With bituminous or semi-bituminous coals,** there are two distinct phases in the combustion process: first, on heating, the distillation and burning of the volatile hydrocarbons, leaves behind a mass of porous coke; second, the burning of this coke takes place exactly as the anthracite is burned. The distillation of the volatile matter introduces, therefore, a period during which the coal absorbs heat instead of giving it out. The extra volume of gas given off requires a freer supply of air than the hard-coal fire.

**63. The two great requirements for efficient combustion are:** (a) thorough "scrubbing" of the coal (or coke and volatile gases) with air, so that each particle of combustible receives its necessary oxygen within the smallest possible space of time; (b) the maintenance of both air gases and coke at a temperature above the ignition point.

Digitized by Google

**64. Types of furnace and stoker:** Hand firing always necessitates a horizontal or slightly inclined grate, so that coal may be fired through open doors all over the surface of the grate; most of the air is fed through the fire from below the grate. In the case of anthracite practically no air is admitted over the fire, because the compact nature of the small sizes of anthracite makes the use of air blast generally a necessity, and more than enough air can be supplied from below the grates. With bituminous coal, not enough air can be supplied from below, and some must be admitted by way of the fire doors or other openings for the purpose above the fire. The required reverberatory action for soft coals must be obtained chiefly by methods of firing. Regenerative action can be improved by the use of Dutch oven furnaces, in which the whole furnace is roofed over with fire-brick, which reflects heat instead of absorbing it, raising the temperature of the furnace. The soft-coal furnaces should always have as high a combustion chamber as possible, but with anthracite coals 18 in. is sufficient. Fig. 14 shows one type.

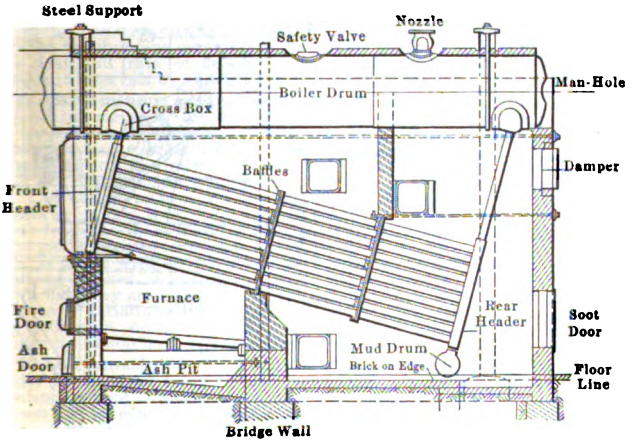

FIG. 14.—Hand-fired grate.

**65. The overfeed stokers** are those in which coal is fed somewhat in the manner of hand firing; green coal is pushed in at one end, or side of the combustion chamber, coked under a combustion arch, and finally burned to ash in a continuous progress across the furnace, the combustion of fixed carbon taking place upon the grates. The best known inclined types are the Roney, Wilkinson, Murphy, Model, Detroit and Wetzel. Fig. 15, shows the Roney type; coal is fed in at the top and worked down by gravity and the continual rocking of the grate bars.

**66. The chain grate types** are the B. & W., Green, Laclede, Illinois, etc. Fig. 16 shows a typical chain grate.

**67. The underfeed stokers** supply coal from below the fire, coke it as it approaches the incandescent top bed, and drive the gases, along with the blast air, through the white-hot coke on top. No combustion arches are required and there are no grate bars, strictly speaking, as little or no combustion takes place on iron—only upon a bed of coal.

**68. Types of underfeed stokers.** The Jones was the original of this type, followed by modifications utilising gravity as well; the principal one of the latter type is the Taylor (Fig. 5), followed very recently by the Riley and the Westinghouse underfeed. Lately, extension grates of the overfeed type and continuous dumping devices have been incorporated in this type of stoker, lowering the combustible content in the ash, and reducing the operating labor.

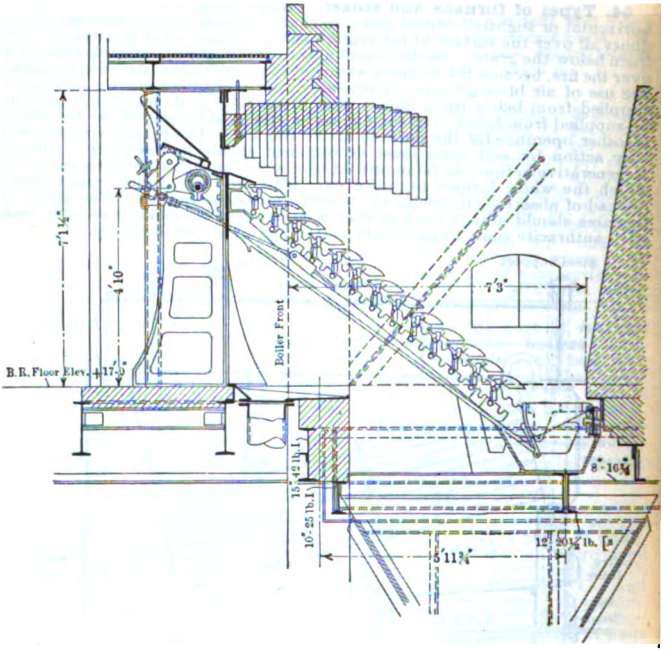

FIG. 15.—Roney stoker.

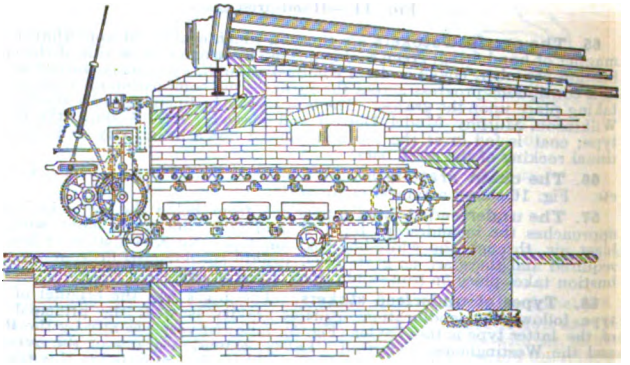

FIG. 16.—Chain-grate stoker.

Digitized by Google

**69. Grates for hand fires are of three types,** stationary, shaking and dumping. Stationary bars are of three principal forms: (a) plain girder-shaped straight bars, spaced from each other ½ in. or ¾ in. by lugs, for air supply; (b) herringbone bars—two straight girder bars about 4 in. to 6 in. apart, cast with herringbone-shaped tie ribs; (c) pinhole bars, for burning sawdust, fine dust and culm, tan bark and similar materials. Rocking and shaking grates are made in a multitude of variations of these simpler forms; and are so arranged that the bars may be rocked in groups, to aid in cleaning the fire, or overturned to dump entirely.

**70. Hand stoking of hard coals** is done in the following manner. Coal, generally of small size (No. 2 or No. 3 buckwheat), is thrown well over the fire, and maintained about 6 in. to 8 in. thick and under considerable blast (1.5 in. to 2.5 in. of water). As fast as a hole blows through any portion, it is covered with fresh coal. This implies frequent firing, and in order to minimise the inrush of cold air at open fire doors some form of balanced draft is very desirable. Portions of the fire are allowed to burn out and are then dumped bodily and fresh fire raked over the bare grate. **With shaking grates** the dumping periods may be farther apart—4 to 8 hr., depending on the coal and rate of firing, as part of the ashes are removed at more frequent intervals by shaking the grate without opening the fire doors.

**71. Bituminous coal can be hand fired in two ways:** the alternate and the coking methods. In the first method, one side of the fire is at the period of hottest combustion while firing green coal on the other, to provide the necessary heat to volatilise and ignite the large volume of gas given off. When this green coal has finished giving off gas and becomes well coked and white hot, the other side, now burned out, is fired. In the coking method, the front part of the grate near the fire doors is made solid and is called the dead plate; green coal is fired upon this, under a coking arch, and receives enough heat from the main body of the fire and from this arch, to become coked. The gas thus given off passes out from the coking arch over the hot part of the fire, is mixed with air admitted over the fire, and thus ignited. The green coal, now coked, is pushed back over the hot part of the fire. As portions burn out, they are dumped and fresh coke raked over the bare grates. There are many variations in the manner in which these operations are performed, depending on the kind of coal. One man can ordinarily take care of one boiler up to 600 h.p., or two boilers at the utmost.

**72. Automatic stoking in the overfeed type** occurs almost in the same order as the hand firing of bituminous coal, except that all the processes, feeding, coking, segregation of ash, and sometimes dumping, are done by power and are continuous, instead of intermittent. The advantage in avoiding irregularity in the processes is obvious.

**73. Automatic stoking in the underfeed type** requires no regenerative devices in the furnace (such as the coking arch), since the gases and the air are mixed by passing through the bed of coal together and are finally heated by direct contact with the incandescent coke, before issuing into the furnace. The underfeed stokers are capable of almost unlimited forcing without serious loss of furnace efficiency, and are much lower in maintenance costs than the overfeed types, as no hot fire is carried on cast-iron parts.

**74. Maintenance costs of stokers.** The maintenance of Roney stokers with good coal, varies from about $0.10 to $0.12 per ton fired; the Murphy, Model, Detroit, Wetsel and Wilkinson vary from $0.11 to $0.14, the higher cost being due to the use of long bars in the fire, which are injured only in about the lower third, necessitating the scrapping of about two-thirds of the bars practically uninjured. With the Roney finger grate, the parts actually in the fire are separately removed, and consequently the efficiency of use of the metal is higher. Chain-grate stokers are comparable in maintenance with the Murphy type. Jones stokers require about $0.04 to $0.06 per ton fired for maintenance, and the Taylor stoker from $0.025 to $0.04 depending on the coal. Highly volatile coals, which must be fired thinner on account of clinkering, use up more iron, as the heat is nearer to the fingers and retorts.

**75. Stoker labor.** One stoker operator to each four stokers, and one coal passer to rake up siftings for each five stokers is good practice for the Roney type. The size of the stoker makes comparatively little difference, and hence the larger the stoker the better. One stoker operator for 6

Digitized by Google

stokers, and one coal passer for raking siftings to 6 stokers, is good practice for the Green or B. & W. types. One stoker operator to 15 stokers is needed for the Taylor, but no coal passers, as there are no siftings. The Jones type requires about the same labor as the Green, as the ashes must be raked out by hand.

**76. The rate of combustion for hand fires** is normally 10 lb. to 12 lb. of coal per sq. ft. of grate for anthracite, and 15 lb. to 20 lb. for bituminous coals. Under forcing the rate may go as high as 80 lb. per sq. ft. of grate, with forced draft. For power plants the usual maximum is 40 lb. to 50 lb. of soft coal.

**77. Natural or chimney draft is common for bituminous coals.** On hand fires 0.3 in. to 0.6 in. water draft at the breeching will generally produce rated capacity from the boiler; 0.3 in. draft at the breeching will produce rated capacity on the overfeed slope-grate types with high percentage of air space (35 per cent. to 45 per cent.). With the restricted types (Wilkinson) and the chain-grate stokers, where the air space is only 8 per cent. to 15 per cent., the required draft to produce rating is usually 0.4 in. to 0.5 in.

**78. Forced draft with underfeed stokers and anthracite hand fires** is practically a necessity, as the resistance through the fires is very much greater (Par. 80). The small sizes of anthracite pack very closely, and in 6 in. or 8 in. thickness may offer as much as 1 in. to 2 in. difference of pressure above and below the fire. In the underfeed stokers the fire is much thicker than in the overfeed type (the latter is about the same as hand-fired bituminous grates or 10 in. to 14 in.), or usually about 2 ft. 6 in. or 3 ft. thickness of fuel bed.

**79. The amount of air required** varies with the volatile content of the coal. The combustible constituents are carbon, hydrogen and sulphur. As far as heat and air supply are concerned, the carbon and hydrogen alone are important, the sulphur seldom exceeding 3 per cent. being low in heat value.

$$C + O_2 = CO_2 \tag{15}$$

$$\underbrace{2H_2}_{2\text{ vol.}} + \underbrace{O_2}_{1\text{ vol.}} = \underbrace{2H_2O}_{2\text{ vol.}} \tag{16}$$

The combining weights are in the proportions of the molecular weights, so that

$$12\text{ lb. C} + 32\text{ lb. } O_2 = 44\text{ lb. } CO_2 \tag{17}$$

$$1\text{ lb. C} + \tfrac{8}{3}\text{ lb. } O_2 = \tfrac{11}{3}\text{ lb. } CO_2 = 3.67\text{ lb. } CO_2 \tag{18}$$

Air is 20.9 per cent $O_2$ and 79.1 per cent. N by volume, and 23.6 per cent. $O_2$ and 76.4 per cent. N by weight, so that, as 1 lb. C requires 2.67 lb. $O_2$, it will require $\frac{1}{0.236} \times 2.67 = 11.30$ lb. of air per lb. of carbon. Similarly, hydrogen requires 34 lb. of air per lb. Then the air required per lb. of any coal will be given by

$$(\text{fraction C per lb.}) \times 11.3 + (\text{fraction H per lb.}) \times 34 = \text{lb.} \tag{19}$$

air required per lb. of coal.

The theoretical amount cannot be used because mixing is imperfect. Usually 18 lb. of air per lb. of coal are supplied for underfeed stokers and 20 lb. to 24 lb. for overfeed and hand fires.

**80. Automatic damper regulators** are used to maintain substantially constant boiler pressure under variable load. A diaphragm operated by steam pressure controls a pilot valve admitting water or oil under suitable pressure to a cylinder which in turn operates the damper lever. If increase in load causes drop in pressure, the diaphragm and pilot cause the pressure cylinder to open the damper wider, increasing the draft and the rate of combustion, thus making more steam to recover the proper steam pressure; and *vice versa*. This device may be employed in the stack or breeching for natural draft; or it may control the fan-engine throttle for forced or induced draft, producing the same results.

**81. In the balanced-draft systems,** a steam pressure regulator controls the forced-draft fan, and a combustion-chamber pressure regulator controls the stack damper or induced-draft fan, so as to maintain zero pressure difference over the fire. This is specially advantageous for hand firing, as the fire doors may be opened and shut without a rush or cold air over the fire. It is also a convenience with any forced-draft stoker.

Digitized by Google

**82. The accessories of the automatic stoker** consist of the forced-draft fan (if required), the stoker engine, and usually, for overfeed stokers—a slice bar and a poker, needed occasionally for obstinate clinkers. In the later types of underfeed stokers, automatic dumping devices are attached, which eliminate the need of hand manipulation of the fire altogether (Fig. 5).

**83. The stoker engines** required with all stokers except the Jones and the Wilkinson, may be of any standard type. The slope-grate overfeed stokers require about 1.5 to 2 h.p. per stoker, the highest being for the largest sizes—say 150 in. in width. Chain grates require 2 to 3 h.p.; underfeed stokers, 3.5 to 4 h.p. per stoker. The Jones type has a steam cylinder attached individually to each plunger and requires no other drive. The Wilkinson type generally has a hydraulic cylinder operating each stoker.

**84. Furnace efficiency** is defined in Par. **27**. Its value for hand fires may be brought up to 94 or 95 per cent. but seldom runs higher than 90 per cent. in regular operation. Automatic stokers can be made to operate at efficiencies as high as 96 to 97 per cent. It is a question chiefly of adequate air supply, intimate mixture of gases, and high temperature.

**85. Flue-gas analysis. The Orsat apparatus** is the simplest and commonest means of analyzing flue gases. It appears in several forms, all of which employ some form of graduated glass gas-measuring chamber, usually waterjacketed, and has means for exposing the sample of gas successively to solutions of potassium hydroxide, potassium pyrogallate, and cuprous chloride (generally the acid solution), for removing $CO_2$, $O_2$ and CO, respectively. The gas is returned to the measuring chamber after each absorption, to measure the reduction of volume. Several automatic machines have been devised for measuring and recording $CO_2$ content in flue gases continuously; but it is now well known that $CO_2$ measurement alone is an insufficient indication of boiler efficiency. Flue temperature and sometimes the full gas analysis are desirable. The absorption of CO is particularly troublesome, as a rule, because the cuprous chloride must be used fresh, and is apt to throw off the absorbed CO if diluted; this also may happen in the Elliott apparatus. **The Elliott apparatus** differs from the Orsat in using long burettes and pipettes for greater accuracy, and the pouring of the absorbents through the absorbing chamber by hand; also, an explosion pipette for measuring the unburned hydrocarbons is added. **The Hempel apparatus** is still more accurate and refined, but is strictly a piece of laboratory apparatus. The Orsat type is made in easily portable form for use at the boiler.

**86. Smoke consists chiefly of unburned carbon** suspended in the flue gases; it may be in the form of particles of unburned coke blown up from the fire by heavy driving or high blast, or in the finely divided lamp-black form, developed by the breaking up of hydrocarbon gases, deficient in air, and exposed to high temperature. The latter form is chiefly indicative of bad combustion; the cure consists of thorough mixing of volatile matter and air in the furnace, and the maintenance of a high temperature of this mixture until combustion is complete, or in other words, until there is no more flame. In so far as any furnace or method of firing accomplishes these two things, in that degree it will be smokeless.

**87. Specifications for stokers** should cover the following: (a) general, and terms of delivery and erection; (b) drawings of stokers and dimensions of boilers to which they are to be attached; (c) operating conditions of boilers and rating; (d) general description of stokers; (e) dampers, doors, drive, and labor used; (f) fan requirements, foundations, air ducts and brickwork; (g) tests and operating conditions for tests, including full description and proximate analysis of coal to be used; (h) guarantees, capacity, efficiency, labor to operate, gas analysis, smoke, maintenance; (i) time of shipment, price and terms of payment; (j) detailed description of stoker and all parts.

**88. The cost of automatic stokers per rated h.p. of boiler** varies but little with size, as most of the stokers are made up of parts such that increase in size means merely increase in unit structure. The price is given delivered but not erected, although superintendence of erection is included; common labor for erection is furnished by the purchaser. The cost of Roney and other step-grate stokers is from \$3.17 to \$3.91 per rated boiler h.p., average \$3.60; chain grates, \$6.20 to \$7.00, average \$6.60; underfeed (Jones type), \$3.70 to \$4.76, average \$4.44; underfeed (gravity plunger).

Digitized by Google

$5.45 to $6.10, average $5.65. The last type can also be listed at $495.00 per retort, a retort yielding about 86 rated boiler h.p.

**89. The forcing capacity** of these different types is extremely variable; the overfeed step-grate types usually cannot exceed 200 per cent. of rating; the chain grates are about the same. The underfeed types are readily reaching 300 per cent. and over. The cost per rated h.p. is therefore not entirely fair as the sole criterion.

**90. Cost figures from a very large stoker installation** using three types are as follows:

| | Rating | Cost per h.p. | Rating | Cost per h.p. |
|---|---|---|---|---|
| Step grate..... | 100 % | $3.17 | 200 % | $1.59 |
| Chain grate with blast... | 100 % | $6.55 | 266 % | $2.46 |
| Gravity underfeed..... | 100 % | $5.77 | 325 % | $1.78 |

The weight of the step-grate stokers is about 500 to 550 lb. per rated boiler h.p.; chain grates, 1,300 to 1,400 lb.; underfeed types (gravity), 550 to 630 lb.

## CHIMNEYS

**91. Chimney draft** is based upon the difference of specific gravity of cold air and heated air. The column of warm air in the chimney exerts a pressure per sq. ft. at the base of $h\gamma$, where $h$ is the height in feet and $\gamma$ is the density of hot gases in lb. per cu. ft. The pressure of the outside air for the same height is $h\gamma_2$, where $\gamma_2$ is the density of cold air in lb. per cu. ft. The motive force is therefore the difference of these two, or $h(\gamma_2-\gamma_1)$, in lb. per sq. ft.

**92. Formula for chimney draft.** For ordinary use,

$$D_1 = H\left(\frac{7.64}{T_2} - \frac{7.95}{T_1}\right) \tag{20}$$

Where $H$ = height of chimney in ft., $D_1$ = intensity of draft, inches of water, $T_1$ = absolute Fahr. temp. of chimney gases, $T_2$ = absolute Fahr. temp. of outside air, and $P_2$ = observed atmospheric pressure, lb. per sq. in. For high altitudes above sea level:

$$D_1 = 0.52\ HP_2\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \tag{21}$$

This gives the maximum theoretical draft with no flow taking place. The actual draft obtained is about 20 per cent. less, due to chimney friction, and head required to create velocity of gases.

**93. Kent's draught formula** is

$$H = \left(\frac{0.3\ \text{h.p.}}{E}\right)^2 \tag{22}$$

$$E = A - 0.6\sqrt{A} \tag{23}$$

Where $E$ = effective area of chimney, $A$ = actual area, (cross-section) of chimney, $H$ = height at top in ft. above grates and h.p. = total connected boiler h.p.

Based on a maximum combustion of 5 lb. coal per rated B.H.P. per hr., this formula may be modified to

$$H = \left(\frac{0.06\ W}{E}\right)^2 \tag{24}$$

where $W$ = total lb. coal fired per hour under connected boilers. This form is more suitable for high rating conditions.

**94. Meyer on chimneys.** Meyer* assumes a combustion rate of 4 lb. of coal per hour per boiler h.p. and 500 cu. ft. of flue gas per lb. of coal. In his table on chimneys referred to in the footnote he gives the friction loss for square steel flues; for brick it is 33 per cent. greater; for rectangular steel flues with sides as 1 to 2, it is 7 per cent. greater; for circular steel flues, 13 per cent. less.

* Meyer, H. C., Jr. "Steam Power Plants;" McGraw-Hill Book Company, Inc., 1912; Chap. XIII. Table XXXIII.

| 240 | ..... | ..... | ..... | ..... | 12,378 | 14,293 | 15,980 | 17,505 | 303.53 | 314.16 |

For pounds coal burned per hour for any given size of chimney, multiply figures in table by five.

Chimneys 25 per cent. larger are recommended for low-grade bituminous coal in middle and western states.

**96. Chimney design** must be based upon kind of coal required. For overfeed stokers and hand fires, Fig. 17 (from B. & W. 1913 issue of "Steam") gives the usual draft required for various coals.

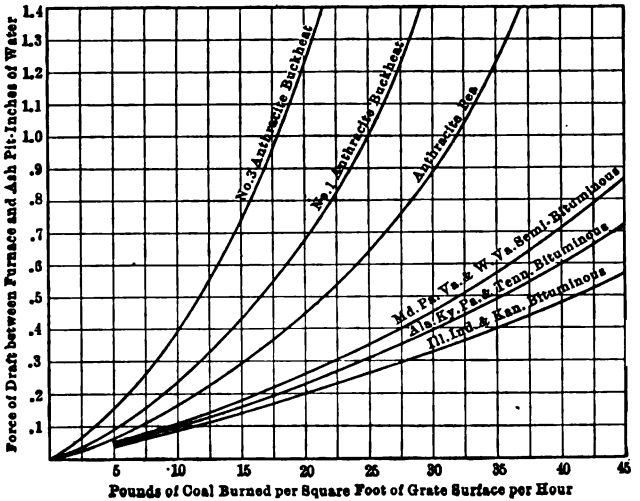

FIG. 17.—Draft for various coals.

Digitized by Google

**The draft loss** through a B. & W. boiler **with standard baffling, clean,** varies from 0.10 in. or 0.15 in. at rating, to 0.29 in. to 0.45 in. at 200 per cent. rating and 0.54 in. to 0.65 in. at 300 per cent. rating. The loss in flues of fairly uniform cross-section is given as 0.1 in. per 100 ft. straight flue, and 0.05 in. for 90 deg. bends. But in the irregular flue shapes often necessary, double these values are not infrequent (Meyer). The draught loss through economizers varies from 0.25 in. to 0.70 in. The sum of all these losses gives the required chimney draft. The diameter is computed (Par. **96** and **97**) from the weight of coal burned. **With stokers using blast** it is necessary only to allow 0.1 in. **draft** over the fire at maximum capacity, as the only function of the stack is to draw off the gases without pressure in the furnace, the resistance of fire bed and stoker being overcome by the blast pressure.

**97. Chimneys are built of the following materials:** (a) red brick, fire-brick lined; (b) radial buff brick, fire-brick lined; (c) reinforced concrete, lined; (d) steel plate, lined; (e) steel plate, unlined. For natural draft, the radial brick, the lined steel plate and the concrete types of chimney are in general use.

**98. Brick chimneys.** The red-brick chimney cannot be less than 0.7 ft. thick at the thinnest portion; in other respects it is designed for stability against a wind pressure of 50 lb. per sq. ft. and against crushing. The walls, therefore, are always thicker at the bottom, and the stack is tapered. This type is not often used for power stations. Radial-brick chimneys may be 0.58 ft. thick at the thinnest part, as the brick is specially moulded; the cross-section is always circular, and tapers in the same manner as red-brick chimneys. Brick chimneys are the most durable of all the types. The fire-brick portions of lining need be carried up only 30 ft. above the grates.

**99. Steel chimneys** have the advantages of lightness and strength, but since they are better conductors of heat, must be lined with brick for heights over 75 ft. except in forced-draft installations. They must be carefully inspected and painted from time to time, as they are subject to deterioration by corrosion.

**100. Reinforced concrete** is much stronger than brick and will stand high tensile strains like the steel chimney. The stack is therefore often built straight like the steel chimney, and is always considerably lighter than brick, as it may safely be much thinner. It is usually poured in 5-ft. or 6-ft. sections, which may be carried up a section a day, making erection rapid. No lining is required other than the short section of fire-brick above the grates (30 ft.). It is one of the cheapest and most durable forms if well designed and built, but like all reinforced concrete, is dependent upon care and watchfulness during construction.

**101. Foundations for brick chimneys** are now made almost exclusively of concrete, and are designed on the basis of proper bearing values, like any other foundation. They are usually spread or stepped out at the foot, in order to provide sufficient resistance to overturning from wind pressure (Par. **590**).

**102. Cost of Brick Stacks**

| Approx. boiler h.p. | Height | Diameter | Diam. square base outside | Price |
|---|---|---|---|---|
| 85 | 80 | 2 ft. 1 in. | 7 ft. 5 in. | 598.00 |
| 135 | 90 | 2 6 | 8 3 | 786.00 |
| 200 | 100 | 2 11 | 9 10 | 1226.00 |
| 300 | 110 | 3 7 | 10 2 | 1492.00 |
| 450 | 120 | 4 3 | 11 2 | 1785.00 |

Brick stacks may be figured on a basis of $12.00 per thousand for laying with masons at $0.55 per hour.*

**103. The cost of concrete stacks** is about 5 to 10 per cent. less than brick (Par. **105**).

* Further cost data may be found in Gebhardt's "Power Plants," Wiley, 1912.

Digitized by Google

**104. The cost of steel stacks** may be figured on a basis of $0.045 per lb. of steel erected.

## MECHANICAL DRAFT

**105. Limitations of natural draft.** From the figures in Par. 91 to 96, it is evident that for high rates of combustion the stack becomes impracticably high, or the sensible heat loss due to high flue temperature becomes too large for economy. To mitigate this, mechanical or artificial draft of some form may be employed.

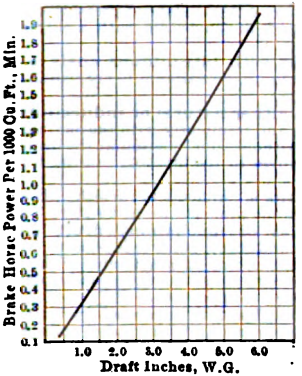

FIG. 18.—Required horse-power for forced-draft fans.

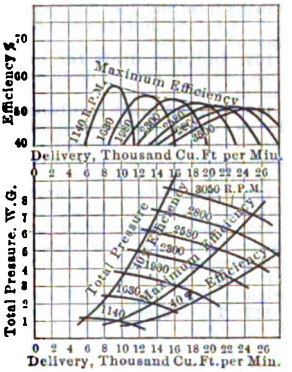

FIG. 19.—Characteristics of 24 by 30 in. forced-draft blower.

**106. The theoretical pressure produced by a revolving fan wheel** is given by Murgue as

$$H = \frac{U^2}{g} \qquad (25)$$

where $H$ = maximum pressure difference, between fan suction and discharge, in feet of air; $U$ = velocity of fan blade tips, feet per second; and $g = 32.2$, acceleration due to gravity. Air pressure in inches of water column is generally referred to in blast and draft.

$$h = \frac{SH}{144p} \qquad (26)$$

where $h$ = inches of water pressure; $S$ = weight of 1 cu. ft. air at 75 deg. fahr. (usual room temperature), or 0.074495 lb.; and $p$ = pressure of 1 in. water column in lb. per sq. in., or 0.0361 lb.

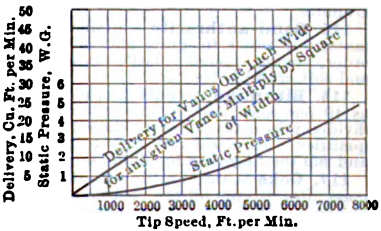

FIG. 20.—Power and volume of forced-draft fans.

$$U = \frac{2\pi rn}{60} \qquad (27)$$

where $r$ = radius to tip of blade in inches and $n$ = r.p.m. Hence

$$h = \left(\frac{2\pi rn}{60}\right)^2 S = C(rn)^2 S \qquad (28)$$

Digitized by Google

Fig. 18 gives the h.p. required at any pressure, for average fans. The characteristics of a forced draft fan for underfeed stokers are given in Fig. 19. The static pressure and volume of any size fan, at any speed, can be found from Fig. 20.

**107. Forced draft.** If the fan is placed so as to blow under the fire, the pressure is greater than atmospheric; this system is termed forced draft.

**108. Induced draft.** If the fan suction is connected to the boiler flue, and delivers to the stack, the pressure in the furnace and ashpit is less than atmospheric; this system is termed induced draft. The two systems may be used together, one fan forcing air through the fire, and the other drawing from the flue, maintaining a more or less balanced pressure over the fire. A forced draft fan also may be used, in connection with a chimney to draw off the gases.

**109. Induced draft for hand fires with bituminous coals** may be substituted for natural draft since the required maximum is not usually over 2 in. of water.

**110. Forced draft combined with either natural or induced draft** is always used with the underfeed stokers and frequently with the chain grates. Forced draft cannot be used alone, as without some suction at the breeching, there would be pressure above atmosphere in the fire-box, causing flame to issue from all openings.

**111. Cost data on blowers and fans** are difficult to furnish; about the only factor remaining nearly constant is the price per lb. at $0.15 to $0.17.

**112. The comparative advantages of mechanical draft** are: (a) greater forcing capacity than with natural draft, since it is easy to produce much greater differences of pressure than are at all practicable with stacks; (b) entire flexibility of control; (c) better combustion conditions with balanced draft arrangement; (d) low cost of apparatus.

**113. The objections to mechanical draft** are increased operating cost due to energy consumption by driving apparatus, and increased maintenance cost, which are balanced against the low maintenance of stacks. But the energy consumption (of steam, for turbine drive, say) is not a net loss, as it may be profitable to use the steam exhaust in feed heating, and the stack requires a certain loss of fuel due to flue gas temperature, in order to operate. This temperature can be lowered when using induced draft. **Forced-draft fans** have low maintenance costs, as they handle cool air; **induced-draft fans**, however, are likely to have high maintenance, as they deteriorate from handling hot flue gases.

## PROPERTIES OF FUEL

**114. Anthracite, or hard coal,** contains very little volatile matter; is mainly fixed carbon and ash; is difficult to ignite; hard and bright fracture, not soiling the fingers in rubbing; oldest coal formation, being next to graphite.

**115. Semi-anthracite** contains a little less fixed carbon, more volatile matter; is easier to ignite and softer. **Semi-bituminous** is the next in order, having enough volatile matter to coke, with moderately long flame, and soft crumbly fracture.

**116. Bituminous coals** are rich in volatile matter, which may be as high as 40 per cent.; usually fairly low in ash—5 to 9 per cent.; and may be divided into many different classes with regard to flame, caking and coking qualities. They are very easy to ignite, brittle and dull fracture, crumbly, and soil the fingers in handling, due to softness.

**117. Coke** is the resulting fixed carbon and ash which remains a porous mass after driving off the volatile matter from a bituminous or semi-bituminous coal. It is largely a product of the coal gas industry; but as a power station fuel, its price is practically prohibitory. Oven coke, which is very hard, is used for blast furnace and crucible furnace work.

**118. Lignite** is a more recent formation than the bituminous coals and is hardly distinguishable from the lower grades of these; it is non-fibrous, and often brownish in appearance, whereas the coals are all black; absorbs oxygen and gives off $CO_2$ at ordinary temperatures. It contains quantities of oxygen and the volatile matter given off is mainly $CO_2$, which distinguishes the lignites still further from the coals, whose volatiles are chiefly hydrocarbons.

**124. Peat** is the most recent of the formations. High-bog peat is formed from swamp moss, etc.; low-bog peat is formed from grasses around low bodies of water. They show the fibrous structure of vegetable origin, and range in color from ochre to brown and black; are very soft in texture, with no fracture; carry large moisture, oxygen and nitrogen content; the volatile matter is poorly combustible, containing largely $CO_2$.

**125. Wood** is still higher in oxygen and nitrogen, up to 40 to 45 per cent., with carbon from 45 to 49 per cent. Its scarcity and cost make its use as a power station fuel impossible except for saw mills and logging camps where the unmarketable waste may be profitably used.

**126. Briquettes*** are small artificial lumps of solid fuel made up by pressing peat, bituminous slack or anthracite culm, with a suitable tarry binder, so as to recombine the soft peat or unmanageable coal dust into a convenient lump form. Briquettes behave somewhat like lumps of soft coal, but usually are very troublesome in giving smoke. The cost of briquetting presses, and the need of suitable inexpensive binder, have prevented the wide use of briquettes in America. With peat briquetting is practically a necessity.

**127. Mineral oils** have their source in crude petroleum. The heavy oil engines, such as the Diesel and the Junkers run on raw petroleum; many of the smaller engines, however, are designed for kerosene and gasolene.

**128. Gas for power production** may be natural gas,† producer gas, coke-oven gas,‡ or blast-furnace gas.§ Illuminating gas is too expensive to use for anything but very small isolated plants. See Par. **26**, **27** and **28**.

**129. The main feature in the use of gas** is the engine compression pressure which is practicable; blast-furnace gas, being lean and much diluted with neutral matter, will stand very high compression; producer gas, natural and coke-oven gas, being richer (especially in hydrogen), cannot be compressed as much.

**130. The cost of anthracite No. 1, No. 2, or No. 3 buckwheat** is about $1.10 to $2.50 per ton at the plant in quantity. The mine cost is not over $1.00 to $1.40. **Bituminous coal** costs from $2.00 to $4.50 at the plant. The cost averages $0.085 to $0.095 per million B.t.u.

**131. Fuel oil costs from** $0.01 to $0.03 per gal. The cost averages about $0.090 to $0.094 per million B.t.u., in the oil-burning districts. While its cost per million B.t.u. is about the same as coal, or somewhat better, in the districts where it is available, it has a further advantage in the better boiler efficiency obtained, and in the elimination of some of the power-station auxiliary apparatus.

**132. Natural gas costs** $0.07 to $0.085 per million B.t.u. All of these figures apply chiefly to large consumers; the prices will go up considerably for small plants.

## WATER SUPPLY AND PURIFICATION

**133. Boiler feed.** Boilers must be fed with fresh water of reasonable quality; in general, if a water is not potable, it is not fit, as it stands, for boiler feed. Wells, fresh-water lakes, rivers and ponds are the prime sources.

**134. Water analysis** to determine the value of a water as boiler feed should be performed by a chemist; but the ordinary tests for hardness, with standard soap solution, hydrochloric acid and methylorange, may readily be carried out in the plant in conjunction with water-softening apparatus.

**135. The dangerous impurities** are sulphuric acid (or other acids if the water has been contaminated by factories), grease and oils in quantity,

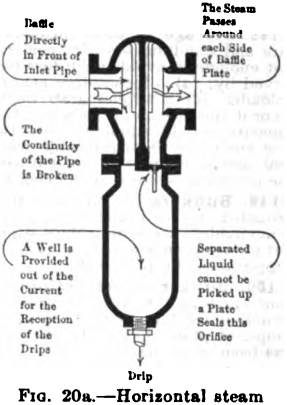
Digitized by Google

and the natural scale-forming salts such as magnesium, iron and calcium carbonates and sulphates.

**136. The treatment of feed water** has been outlined in Par. **49** to **51.**

**137. The use of condensate** returned from surface condensers is usually a valuable way of eliminating most of the boiler incrustation. The only drawback lies in the presence of oil and grease in the condensate, if the condenser serves a reciprocating engine. Quantities of oil in excess of 0.4 to 0.5 g. per gal. are objectionable, as they collect whatever soft scale may be present in the boiler and form a brown mass which bakes on the tubes and has the same effect as hard scale.

**138. Oil and grease extractors,** designed on the same general lines as steam separators are employed between the engine and condenser, in order to keep down the amount of oil passing into the condensate. As a matter of fact, the baffles placed in these devices are really of very little use; it is the reservoir effect of the extractor in slowing down the current of steam which really does the work. Where turbines are the prime movers, no grease or oil separators are required. Fig. 20a shows a typical separator.



Baffle Directly in Front of Inlet Pipe
The Steam Passes Around each Side of Baffle Plate
The Continuity of the Pipe is Broken
A Well is Provided out of the Current for the Reception of the Drips
Separated Liquid cannot be Picked up a Plate Seals this Orifice
Drip

FIG. 20a.—Horizontal steam separator.

## COAL AND ASH HANDLING

**139. Coal is delivered** to the power plant of any size, either by barge, schooner or railroad car. Handling coal by truck is practically too expensive for use in any but small isolated plants.

**140. Unloading** may be done by a grab-bucket digger, or if delivered by car, an elevated trestle may be employed, dumping from the car bottoms. For most of the large plants, a coal tower with a 1-ton or 1.5-ton clam-shell digger is employed to unload and hoist the coal high enough to pass by gravity through crushers and weighing scales, and finally to conveyors or coal cars. In smaller plants, a locomotive crane, or monorail telpher, may perform the same work and also serve the storage yard. Towers may be either steam or electric driven; the former is generally the cheaper and more rugged construction.

**141. Crushers** are heavy rolls of cast iron, studded with teeth, geared together in such fashion as to crush the coal to small size; some spring or relief device must be fitted to allow harder materials to pass through, such as link chains, sprags and occasionally a car coupler. Crushers are not needed for anthracite.

**142. Conveyors** are of five principal types; scraper, reciprocating, belt, bucket and suction. **The scraper conveyor** consists of flights or paddles rigidly fastened upon a special bar-link chain, and dragged along in a trough shaped to the flights. The **reciprocating conveyor** is very similar, but only moves a few feet forward and backward. The flights are so hinged that on the backward stroke they lift out of the coal and trail over the top, digging in again when the chain reverses.

**143. Belt conveyors** consist of wide rubber or textile belts travelling continuously over idlers spaced from 2 ft. to 4 ft. apart, and with the outer pulleys tilted up to trough the belt. The belt conveyor is not suitable for ashes.

**144. The bucket conveyor** has separate buckets from 24 in. to 48 in. square, either fixed rigidly to long-pitch side links, or pivoted in the center, so as to remain vertical. In the latter case, all of the conveyor is malleable iron except the rails and framing. It is exceptionally suited to handling ashes.

Digitized by Google

**145. The suction conveyors** are used only for **ashes**; coal is too heavy and packs too readily to be handled in this manner. The suction is usually provided by a high-speed centrifugal blower, attached to the outlet. The rest of the equipment consists merely of 10-in. and 12-in. cast-iron pipe lines with swing-door openings at which the ashes are admitted. The drawback to this system is the deterioration of the fan from grit, and all turns and elbows from abrasion. If the ashes are too wet, the blocking of the pipes is practically certain to give trouble.

**146. Comparisons of conveyors.** The belt conveyor is very satisfactory on "carry" of coal, but not so good on "lift;" the bucket conveyor is probably the most satisfactory all-around conveyor, handling coal or hot ashes equally well in lift or carry; it is, however, the most expensive.

**147. Another method of conveying is by cable cars**; where possible this gives the cheapest and most satisfactory means of carry.

**148. Storage of coal** outdoors for power-plant purposes requires less care and handling than for coal companies, as the material is turned over fast enough to avoid much loss by weathering. The storage yard may be served by: (*a*) a locomotive crane, (*b*) a gantry crane, (*c*) a Dodge girder unloader, (*d*) a telpher grab bucket operating on an overhead structure, (*e*) or if the storage is in a pit, by a conveyor in a tunnel. Usually the capacity should equal at least two weeks supply, or better, one month. One company having trouble from spontaneous combustion of bituminous coal, uses a concrete pit flooded with water; but this is generally unnecessary, the excessive wetting of the coal being a drawback.

**149. Bunkers** placed under the roof of the boiler house are almost always provided, to feed coal by gravity to the fires. Where external storage is available, two to four days supply in the building is all that is necessary; but in city plants where external storage is impossible, ten days to two weeks supply must be provided.

**150. Bunker construction.** Steel framing with concrete or cinder-concrete lining, faced with granolithic or other hard finish, is the best construction for large work; for smaller work, the suspended type, catenary shape, of plate steel with concrete lining, or simply of reinforced concrete, has been much used.

**151. Hoppers.** Ash hoppers of structural material with brick lining are the standard practice, but reinforced concrete is also being used to some extent. The coal hoppers should always be of sheet steel, $\frac{1}{4}$ in. being the usual thickness; it is good practice to reinforce the hoppers with renewable wearing plates where the abrasion is severest.

**152. Weighing** is done at the hoisting tower (just after crushing) in hoppers carried in knife-edge supports which operate standard beam scales; two sets are required, one hopper receiving the continuous flow of coal from the crusher while the other is being weighed. Reversing gates for the supply, and trip gates for the weighing hoppers are under the control of the weighmaster.

**153. Automatic scales** of the hopper type are in use for anthracite, and are fairly accurate, as the angle of repose and slip of anthracite in the small sizes is very little affected by moisture, and the small size allows ready control of the flow; with bituminous coals they are somewhat unsatisfactory, as the highly variable angle of repose affects the spillage when closing the feeder gates, making the "dribble" a variable quantity. Conveyor scales of several makes are on the market, but not widely used.

**154. There is also a coal meter** for use in pipe downtakes, acting on the principle of a propeller driven by the moving coal, which is very simple and quite accurate for small sizes of coal. It is not yet fully satisfactory for lump coal and run of mine.

**155. Spouting of coal** in closed pipes must always be done at an angle of 45 deg. or steeper to be satisfactory, if the spout is a closed pipe; 8-in. to 10-in. pipes may be used with anthracite; but nothing less than 12 in. should be used for bituminous crushed coal. In designing hoppers and spouts it should be remembered that the intersection of two sides each at 45 deg. from the horizontal, is much less than 45 deg., so that the coal will always hang at such a junction.

**156. The power required by belt conveyors** is given by the following formula:

$$H.P. = \frac{CTL}{1{,}000} + \frac{TH}{1{,}000} \qquad (29)$$

where $C$ = power constant, $T$ = load in tons per hour, $L$ = length of conveyor in feet, $H$ = lift of conveyor in feet, and $B$ = width in inches.

Values of $C$ for material weighing 25 lb. to 75 lb. per cu. ft.

| B (in.) | C | H.P. on account of trippers in belt | B (in.) | C | H.P. on account of trippers in belt |
|---|---|---|---|---|---|
| 12 | 0.234 | 0.5 | 26 | 0.187 | 2.0 |
| 14 | 0.226 | 0.5 | 28 | 0.175 | 2.25 |
| 16 | 0.220 | 0.75 | 30 | 0.167 | 2.5 |
| 18 | 0.209 | 1.0 | 32 | 0.163 | 2.75 |
| 20 | 0.205 | 1.25 | | | |
| 22 | 0.199 | 1.5 | 34 | 0.161 | 3.0 |
| 24 | 0.195 | 1.75 | 36 | 0.157 | 3.25 |

Add 20 per cent. for conveyors under 50 ft. long.

Add 10 per cent. for conveyors between 50 and 100 ft. long.

The formula does not include friction of gear drive. Add about 10 per cent. for the drive and 10 per cent. for each 180 deg. turn idler, exclusive of the head and tail pulleys. Speeds run from 300 to 450 ft. per min.

**157. The power required by flight or scraper conveyors** is as follows:

$$H.P. = \frac{ATL - BWS}{1{,}000} \qquad (30)$$

where $A$ and $B$ are constants in the table below, $W$ = weight of chain and flights in both runs, $L$ = length of feet, $S$ = speed in feet per minute, and $T$ = load in tons per hour.

Values of $A$ and $B$

| Inclination | 0 deg. or horizontal | 5 deg. | 10 deg. | 15 deg. | 20 deg. | 25 deg. | 30 deg. | 35 deg. | 40 deg. | 45 deg. |
|---|---|---|---|---|---|---|---|---|---|---|
| $A$..... | 0.343 | 0.42 | 0.50 | 0.585 | 0.66 | 0.73 | 0.79 | 0.85 | 0.90 | 0.945 |
| $B$..... | 0.01 | 0.01 | 0.01 | 0.01 | 0.009 | 0.009 | 0.009 | 0.008 | 0.008 | 0.007 |

Speeds 100 to 200 ft. per min.

**158. Bucket Elevators and Conveyors**

| Size, buckets, | 12″×12″ | | | 24″×15″ | | | 36″×20″ | | | 48″×24″ | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Spacing..... | 18″ | 24″ | 36″ | 18″ | 24″ | 36″ | 18″ | 24″ | 36″ | 48″ | | |
| H.p. for 100′ vertical lift..... | 0.46 | 0.35 | 0.23 | 1.35 | 1.0 | 0.67 | 3.8 | 1.9 | 3.5 | 2.7 | | |
| H.p. for 100′ horizontal run empty | 1.2 | 1.1 | 0.9 | 1.7 | 1.5 | 1.3 | 2.4 | 1.6 | | | | |
| H.p. for 100′ horizontal run full, anthracite..... | 2.5 | 2.1 | 1.5 | 5.3 | 4.3 | 3.1 | 12.4 | 6.6 | | | | |
| H.p. for 100′ horizontal run full, bituminous coal. | 3.2 | 2.6 | 1.9 | 7.4 | 5.8 | 4.2 | 18.0 | 9.4 | | | | |

Add 5 per cent. for each turn.

**159. Ash handling** is very frequently done by trolley locomotive and side dump cars, in large plants; these allow for thorough quenching before delivering to conveyors for elevation. Of the conveyors, the malleable-bucket type lasts the best in ash service. A skip hoist may be substituted for conveyors, for elevation; and where it can be used, is a most satisfactory means of disposal. Ash bunkers are almost always provided for storage purposes, as in many plants the ash removal from the individual boiler ash hoppers is done on night shift, when cars or boats are not readily available.

**160. Helical or screw conveyors.** The power required is

$$H.P. = \frac{W'LC}{33{,}000} \tag{31}$$

where $W'$ = capacity in lb. per min., $L$ = length in feet and $C = 0.67$ for coal, 1.00 for ashes.

**161. Typical combinations** are: low-hoist grab-bucket tower, containing crusher and scales; belt conveyors, horizontal, to power station; V-bucket or pivoted-bucket elevator, belt distribution at top of building to bunkers. Inclined belts may be used for "lift," but are not too satisfactory. Belts are very good on "carry," however. If the tower is close to the building, bucket elevators may be used both for lift and carry. A very good arrangement is: high towers, performing the whole lift at once, delivery through crusher and scales to cable car for distribution over bunkers. For small or moderate size plants telpher grab buckets offer a satisfactory solution, serving storage yard, cars or boats, and bunkers on overhead monorail structure. The usual system for ash disposal consists of collection from ash hoppers by industrial railway and trolley locomotive, and delivery to skip hoist or bucket elevator for lifting to ash storage pockets, for which the ashes are spouted to cars or barges. The vacuum system is useful for small and moderate size plants; or a single hand car may be enough. Belt conveyors should never be employed for ash handling.

**162. The cost of conveyors** is exceedingly variable and is dictated chiefly by structural conditions. It is almost impossible, therefore, to give unit costs. Belt conveyors of the lengths usual in power station work cost from \$1.10 to \$1.40 per inch of belt width, per foot of conveyor; bucket elevators and conveyors, roughly \$0.18 to \$0.25 per ton capacity per hour, per foot of conveyor.

## STEAM ENGINES

**163. Source of energy.** The steam engine must obtain its energy from the heat drop available by adiabatic expansion between any two pressures. For adiabatic expansion, there must be no heat interchange with the surroundings while the mass of steam in the cylinder undergoes the expansion; therefore a non-conducting cylinder is required. This is commercially unattainable, and consequently the expansion is never truly adiabatic. The heat drop obtainable is always less, if the expansion is not adiabatic.

**164. The thermal efficiency of a perfect engine** working on the Rankine cycle (Par. 166) is given as

$$E_r = \frac{H_1 - H_2}{H_1 - h_2} \tag{32}$$

where $H_1$ = total heat of steam at initial condition (pressure and quality or superheat), $H_2$ = total heat of steam at final pressure after an adiabatic expansion (constant entropy), and $h_2$ = heat of the liquid, at final pressure. For modern steam pressures, superheats and vacua, this possible efficiency does not exceed 35 per cent. for turbines. The usual steam pressures and vacuum for reciprocating engines would not give a higher efficiency than 30 per cent.

**165. The efficiency ratio** for good compound engines seldom reaches 60 per cent., giving an actual thermal efficiency of 18 per cent., 13 per cent. and 14 per cent. are more commonly reached in large size reciprocating engines.

**166. The Rankine cycle** upon which these comparisons are based pre-supposes a non-conducting cylinder, no leakage and no clearance; admission at constant pressure, instantaneous cut-off; expansion adiabatically to the back pressure; exhaust at constant pressure; and since there

Digitized by Google

is no clearance, no compression is required. In the real engine, conduction of heat, leakage, wire-drawing, friction, incomplete expansion, and clearance all tend to reduce the efficiency ratio by adding losses.

**167. A single-expansion engine** is one in which the complete expansion from initial to back pressure takes place in one cylinder; a **compound engine** is one in which the expansion is from the initial pressure to an intermediate pressure in one cylinder, and from this intermediate pressure to the back pressure in a second cylinder. A **triple or quadruple expansion engine** performs the expansion similarly in three or four stages, respectively. All engines using more than one cylinder to complete the expansion are termed **multiple expansion**, in general.

**168. Cut-off** usually takes place at ¼ to ½ stroke in simple non-condensing engines, ⅛ to ¼ in condensing. **The number of expansions** is the ratio of final cylinder volume to volume contained at cut-off; for simple non-condensing engines the ratio is 3 to 4; simple condensing, 5 to 8; compound and triple, etc., 8 to about 50. For power station purposes 16 to 20 is common, with compound condensing units.

**169. Non-condensing engines** exhaust freely to atmosphere, or to a system in which the pressure is atmospheric or a few lb. per sq. in. above; condensing engines exhaust to a condenser in which a partial vacuum is maintained, below atmospheric pressure.

**170. High-speed engines** operate at 350 to 250 rev. per. min., in sizes from 5 h.p. to 500 h.p. **Medium-speed** engines operate at 250 to 150 rev. per min. in sizes from 250 h.p. to 1,000 h.p. **Low speed** engines (generally Corliss types) operate from 100 to 70 rev. per min., in sizes from 400 h.p. to 8,000 h.p.

**171. Single-acting engines** take steam on one side of the piston only; they may be simple, compound or triple expansion; and are always high-speed engines, usually with vertical cylinders.

**172. The slide valve** in the original D-valve form is unbalanced, moving on flat faces; it is unsuitable for large sizes and heavy pressure. Balanced forms of the slide valve, such as the Ball, Skinner, Mackintosh & Seymour grid, etc., overcome some of these objections. **The piston valve**, shaped like a piston, is inherently balanced; it can be made tight, but requires large clearance percentage, on account of length of the ports.

**173. The Corliss valve** is of general cylindrical shape, oscillating over ports parallel to the axis of the valve and crosswise of the cylinder; it can take care of but one function, therefore four are required per cylinder, two for admission and two for exhaust. The preceding types, except the grid, take care of all four functions with one valve. The Corliss valve is always used with a trip or releasing gear to vary the cut-off without changing any other event in the steam admission or exhaust. In all fixed valve gears, it is usually impossible to vary the cut-off without varying other functions at the same time.

**174. Poppet valves** are those in familiar use on automobile engines; but for steam use are generally made double-seated so as to be balanced. They have met with great success in Germany, and are undoubtedly the best type for superheat. They may be used with releasing gears, and require four valves per cylinder, as with the Corliss type.

**175. Jackets for keeping the cylinder hot** with live steam, to reduce condensation in the cylinder, have been used with some success for pumping engines; but have not been successful in many other applications.

**176. Receivers** are used to eliminate variations of pressure between high-pressure and low-pressure cylinders in multiple-expansion engines, due to intermittent exhaust and admission: they must be of large capacity to be effective. **Reheating coils** are sometimes employed to dry the steam passing through these receivers, to improve conditions in the succeeding cylinders. They are of practically no value in engines for power-station service.

**177. Governors** for steam engines are of two principal types: flyball and shaft governors. The flyball type consists of two or more weights or balls supported by movable arms, the whole rotated around a shaft so that centrifugal force tends to throw the balls outward; this tendency is resisted by weights or springs, and the relative movement of the arms made to operate

Digitized by Google

the engine valve gear. In the **shaft governor** the weights are arranged to rotate vertically around the main crank shaft, and attached direct to the eccentrics without the intervention of other mechanism. It cannot be used with slow-speed engines, nor with any form of trip or releasing gear. Inertia effects are introduced in the Rites type of shaft governor.

**178. Either centrifugal or inertia types of governor can be made isochronous,** but are generally only approximately so; isochronism, or complete instability of the governor at all speeds except the correct speed, is undesirable.

**179. Engine frames** are usually made entirely of cast iron, for stationary work; the vertical engines are of the A-frame type in large and small sizes and of the enclosed type, with automatic oiling, for small and moderate size only. Horizontal engines of small and moderate sizes, may be enclosed, with automatic or splash oiling.

**180. Girder frames.** The large horizontal Corliss type engines are made with girder frames connecting the cylinders and the main bearings, for the **standard type**; in the **heavy-duty type**, the girders are completely surrounded by the frame, which is carried down to the sole plate all the way from cylinder to main bearing.

**181. Mean effective pressure** is the average pressure which if exerted during the full stroke would equal the work done by the varying pressures really existing during the course of the stroke. The mean effective pressure (m.e.p.) is obtained from the indicator card as follows:

$$\text{M.e.p. in lb. per sq. in.} = \frac{\text{card area in sq. in.} \times \text{scale of spring}}{\text{card length in inches}} \qquad (33)$$

The shorter the cut-off, the lower the m.e.p. for any given steam pressure and back pressure; consequently the larger the cylinder dimensions become for a given horse-power, other things being constant.

**182. Cylinders are usually so proportioned** as to divide the total work equally between high- and low-pressure cylinders; roughly, for compound engines, the cylinder ratio is given by

$$Rc = \left(\frac{P_1}{P_2}\right)^{\frac{1}{2}} \text{ and } P_2 = (P_1 P_3)^{\frac{1}{2}} \qquad (34)$$

where $Rc$ = cylinder ratio, or ratio of low-pressure displacement to high-pressure displacement, $P_1$ = initial pressure in lb. per sq. in. absolute, $P_2$ = receiver pressure in lb. per sq. in. absolute, and $P_3$ = back pressure in lb. per sq. in. absolute.

This is based on no clearance, no compression, equal cut-off in both cylinders, logarithmic expansion, and receivers of infinite capacity. It is varied in practice by the clearance of both cylinders; by finite receivers and by the effects of wire-drawing.

**183. The speeds usually employed** in America are given in Par. **170**. Snell gives a table of usual English practice, which is slightly higher than American usage.*

**For sizes above 1,750 k.w.,** the speed is from 75 to 60 rev. per min., for Corliss engines. **Piston speeds** range from 350 to 600 ft. per min. in the high-speed engines, and from 600 to 750 ft. per min. in the low-speed, long-stroke Corliss types.

**184. Indicated horse-power** is given by the indicator, and is the amount of power actually developed in the cylinder by the steam. **Brake horse-power** is the actual output at the shaft.

$$\text{I h.p.} = \frac{PLAN}{33{,}000} \qquad (34a)$$

where

$P$ = mean effective pressure, lb. per sq. in.;
$L$ = length of stroke, ft.;
$A$ = piston area, sq. in.;
$N$ = number of strokes per min.

* Snell, "Power House Design," p. 146, Table XLVII.

Digitized by Google

**186. The mechanical efficiency** is given by the formula

$$E_m = \frac{\text{b.h.p.}}{\text{i.h.p.}} \tag{35}$$

where $E_m$ = mechanical efficiency, b.h.p. = brake horse-power, and i.h.p. = indicated horse-power.

$$\text{Friction h.p.} = \text{i.h.p.} - \text{b.h.p.} \tag{36}$$

Lucke gives the formula

$$E_m = 1 - \frac{K_1 - K_2}{(\text{m.e.p.})} \tag{37}$$

where $K_1 = 0.02$ to 0.05, average 0.04; and $K_2 = 1.3$ to 2.0, average 1.6.

**186. Mechanical design** of the steam engine is limited by first cost, efficiency and reliability: these three factors exert influences in varying directions. Low cost per h.p. capacity indicates high rotative speed and simplicity of mechanism. High economy indicates lower speeds, complicated valve gear, multiple cylinders, reheaters and large receivers. Reliability dictates heavily built parts, elimination of small parts, and especially the elimination of small bearings. **The outcome** is that for small powers, moderate speeds and low steam pressures, the simple non-condensing slide-valve engine, throttle governed, is used. Under steady load and speed it has fair economy, and is very reliable. For small electric isolated plant service, the high-speed automatic engine, with shaft governors and piston-valves or balanced slide valves, is used. For higher powers the low-speed condensing engine, either simple or compound, is adopted. The higher economy demanded justifies the increased cost due to low speed and Corliss valve gears; reliability is also provided, since the complex gear is now large enough not to be fragile.

**187. Friction loss,** which causes the difference between brake and indicated power, is made up of bearing friction; piston, valve and rod friction; and windage. The principal bearing friction occurs in the main bearings, crank pins and crosshead slippers, the remainder occurs in the valve gear. **Suitable lubrication** greatly reduces this kind of friction. Piston, valve and rod friction occur in a steam atmosphere where lubrication is at best uncertain. The latter depends upon the type of valve, whether balanced or not; upon the kind and number of piston rings; and upon the condition of the rod packing.

**188. Lubrication of all bearings** is accomplished with engine or machine oil; or prepared grease. In small engines, sight-feed oil cups are commonly used; for large units, a central gravity oiling system piped to all bearings is considered the best practice. In the latter case, the oil is caught after use and returned to filters, whence it is again pumped to the elevated supply tank. In this way copious supplies of oil may be given without great expense and the friction is very much reduced. **Splash oiling** in closed crank-case engines is employed for high speeds and small or moderate sizes. Grease can only be fed by individual compression cups at each bearing.

**189. Cylinders are oiled with heavier lubricants,** whose lubricating qualities in the steam become the same as ordinary engine oil at room temperatures. Cylinder oil is fed into the steam pipe just above the throttle, or into the steam chest: a hydrostatic sight-feed lubricator, or a force pump may be employed. The latter is considered the better method. **Graphite** has been used with much success in assisting cylinder lubrication; the chief difficulty lies in getting it into the cylinder.

**190. The total losses occurring in a steam engine** can be classified as follows: cylinder condensation; leakage; clearance; incomplete expansion; wire-drawing; radiation; mechanical friction.

**191. Cylinder condensation** is caused by the conduction of heat away from the steam through the cylinder walls; the cylinder assumes an average temperature about half-way between steam admission and exhaust temperatures. Consequently the hot in-coming steam gives up heat to the cooler walls; some of this is returned, too late to be of use, during the exhaust stroke. **Moisture in the entering steam** makes this effect worse; but **superheat** much improves it, by increasing the surface resistance to heat transmission.

Digitized by Google

**192. Leakage** occurs past all sliding joints—the joint behaves like an elongated capillary orifice for steam flow; such joints occur at the piston, the piston rod, the valve seat and the valve rod. The means of reducing leakage are generally snap and spring-rings for pistons and piston valves, pressure plates insuring a close fit for flat balanced valves, and sectional metallic or soft packing compressed by a gland, for all rods.

**193. Clearance** is any space left between the valve and the piston, when the latter is at the end of the stroke. It varies from 3 to 4 per cent. of the displacement in well-designed Corliss engines; from 8 to 14 per cent. on high-speed and medium-speed engines; from 15 to 30 per cent. in badly designed or low-price slide-valve and piston-valve engines.

**194. Zero clearance is not possible** in any commercial construction, since piston must have some clearance from the cylinder head, and the steam and the exhaust passages must always have some volume. Clearance necessitates compression, in order to bring the volume of steam trapped in the clearance space to approximately the initial pressure; this has the double effect of cushioning the engine and avoiding loss due to filling the clearance space with fresh steam at each stroke.

**195. Incomplete expansion** is due to the limitations in size of cylinders, which commercially cannot be made large enough to handle the high volumes at low pressure.

**196. Wire drawing** is the term applied to pressure drop between steam chest and cylinder due to insufficient area in the valves and ports, or slow opening of the valve; it reduces the effective pressure and therefore causes a loss.

**197. Radiation** is the heat loss which occurs when the cylinder temperature is higher than that of the surrounding air. Not only the cylinder, but also those parts of the engine which become hot by conduction, radiate heat. The cylinder is heavily lagged (or even jacketed in a few cases) to reduce the loss. This loss amounts to 1 or 2 per cent. of the total heat of steam used by the engine.

**198. Indicated horse-power** is obtained from the indicator card (Par. 184) and was the basis of most guarantees up to a few years ago. Brake horse-power, which is the useful power delivered at the shaft, is now more common.

**199. Non-condensing single-cylinder engines are usually rated** at $\frac{1}{4}$ or $\frac{1}{5}$ cut-off and 100 lb. gage steam pressure; compound non-condensing engines at $\frac{1}{4}$ to $\frac{1}{5}$ cut-off in the high-pressure cylinder and 150 lb. gage pressure; simple condensing engines at $\frac{1}{4}$ or $\frac{1}{5}$ cut-off and 125 to 150 lb. gage pressure. The guarantees should always state steam pressures, back pressures and actual cut-off, instead of the above figures.

**200. The locomobile type** of engine developed abroad and lately introduced in this country is a combination consisting of a tandem compound engine mounted directly on an internally fired boiler. The high-pressure cylinder is in the smoke flue, and the low-pressure cylinder is jacketed by the steam dome. A superheater is also fitted in the smoke box. The advantage of maximum jacketing effect, high superheat, and practically no piping losses, make the fuel economy high. This type of unit is now manufactured in this country, but the advantages of the turbine, coupled with the comparative inflexibility of a single boiler-engine unit, will prevent extensive use of the locomobile in America.

**201. Exhaust steam heating** makes use of the heat wasted by the engine; it may amount to 80 or 90 per cent. of the heat originally in the steam. Consequently, the power is obtained at very low cost for fuel, since most of the ordinary inherent losses are recovered as heat in the heating system. Hence in most industrial plants serving buildings with lighting and power service, non-condensing engines are used. Generally the expense of a condenser to be used during the summer months will not be justified, as the small gain in economy for the year will not offset the fixed charges on the condenser equipment.

**202. Average steam-engine performance.** The brief summary which follows, with a few omissions and additions, is taken from the more extensive tables given in Gebhardt's "Steam Power Plant Engineering."

**203. Water rates vary greatly** with steam pressure, superheat or moisture, and back-pressure. No comparison of water rate alone can be fair, unless the steam conditions are known. Fig. 21 shows typical curves for engines of small and moderate size, and Fig. 22 for large engines. The Rankine-cycle efficiency ratio is the best means of comparison for varying steam conditions. For small non-condensing engines, the efficiency ratio varies from 0.50 to 0.65; condensing lowers the ratio about 0.05 to 0.10.

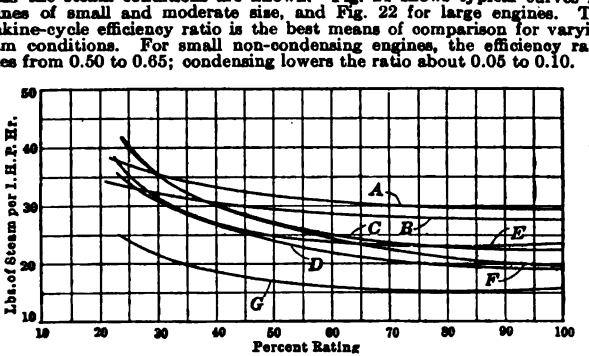

FIG. 21.—Water rates of small engines.

*A*, Automatic single cylinder, non-condensing, pressure = 125 lb., 80 i.h.p.; *B*, automatic single cylinder, non-condensing, pressure = 125 lb., 200 i.h.p.; *C*, automatic tandem compound, non-condensing, pressure = 140 lb., 200 i.h.p.; *D*, automatic tandem compound, condensing, pressure = 140 lb., 300 i.h.p.; *E*, Corliss or medium speed four-valve simple, non-condensing, pressure = 130 lb., 200 i.h.p.; *F*, Corliss or medium speed four-valve tandem compound, non-condensing, pressure = 150 lb., 300 i.h.p.; *G*, Corliss or medium speed four-valve tandem compound, condensing, pressure = 160 lb., 300 i.h.p.

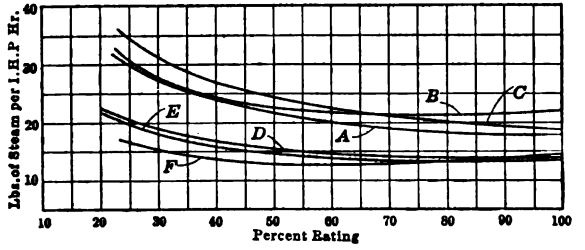

FIG. 22.—Water rates of large engines.

*A*, Automatic tandem compound, condensing, 700 i.h.p., pressure = 150 lb.; *B*, Corliss or medium speed four-valve simple, non-condensing engine, 900 i.h.p., pressure = 130 lb.; *C*, Corliss or medium speed four-valve tandem compound, non-condensing engine, 950 i.h.p., pressure = 150 lb.; *D*, Corliss or medium speed four-valve tandem compound, condensing engine, 900 i.h.p., pressure = 160 lb.; *E*, Corliss or medium speed four-valve tandem compound, condensing engine, 1,500 i.h.p., pressure = 160 lb.; *F*, Manhattan type, double compound Corliss condensing engine, 10,000 i.h.p., pressure = 175 lb.

**204. The thermal equivalent of a horse-power hour** is 2547 B.t.u. Large high-grade engines actually develop a horse-power on 15,600 to 17,000 B.t.u.; small engines, 25,000 to 34,000 B.t.u. Par. **202**, gives these values in terms of B.t.u. per indicated h.p. per min.

Digitized by Google

**205. The effect of raising the back-pressure** upon an engine can readily be seen from the Mollier diagram; the available adiabatic heat drop is re uced and consequently, although the efficiency ratio may not change, the thermal efficiency of the Rankine cycle is reduced, and therefore the thermal efficiency of the actual engine. In other words, the water rate increases. Since the heat drop is less, there will be somewhat more heat per lb. in the exhaust.

**206. Exhaust steam turbines** are of valuable use in connection with non-condensing engines used intermittently. The economy of such engines (say, for rolling mill service) is low, and large quantities of steam are exhausted to the air one moment, and almost none the next.

**207. Regenerators.** The exhaust of several such engines (Par. **206**) is piped to regenerators, which are simply heat reservoirs containing a large body of hot water in contact with the exhaust steam. The effect of the regenerator is to absorb heat, when delivered in excess, by condensation of steam; and to release it upon shortage, by evaporation of some of the water. The slight pressure variations between full delivery and shortage are sufficient to accomplish this.

**208. A low-pressure turbine served by the regenerator** will operate on about double the water rate of high-pressure machine of the same size. The resulting overall water rate for the output of both engines and turbines may be from 20 to 50 per cent. less than with the original engines alone; or the energy delivered by the turbine may be considered as obtained practically for nothing except the fixed charges and maintenance on the regenerator, piping and turbine.

**209. Low-pressure turbines** may sometimes be used in connection with high-grade engines as a convenient means of increasing capacity. The efficiency ratio of non-condensing engines is always much higher than that of condensing engines of the same size (Par. **201**); this is due mainly to the low-pressure cylinder, which has a very low efficiency. The low-pressure turbine has a better efficiency ratio than the high-pressure machine, because the friction of the steam is always less at the lower densities, and the friction is again reduced by the removal of the moisture in the steam before reaching the turbine.

**210. The largest installation of low-pressure turbines** is at the Interborough Rapid Transit Company's 59th-Street Station, New York. Five Curtis turbines of 7,500 kw. maximum rating are individually connected to five compound Corliss engines of 7,500 kw. maximum rating. The steam pressure is 190 lb. gage; vacuum, 28.5 in.; moisture in steam, 1.5 per cent. The net results are: increase of economical capacity, 146 per cent., increase of maximum capacity, 100 per cent. reduction of water rate, 25 per cent. (Stott and Pigott; A. S. M. E. Trans.; Mar. 1910.)

**211. When exhaust turbines are applied to an engine of poor economy,** the saving is even greater. However, there is a limitation to the use of the low-pressure turbine, in that the engines must be built to withstand the extra pressures which result from changing to non-condensing service, and must be in good enough condition to be reliable. It is very bad policy to make such an installation in connection with an old and unreliable engine.

**212. Engine specifications** should cover the following points; (a) Number and location; character of building. (b) Type, service, and manner of connection to load. (c) Principal dimensions. (d) Steam and back pressures, normal and overload capacity. (e) Speed regulation under all kinds of load variation; variation of angular velocity. (f) Satisfactory operation, noise, vibration, etc. (g) Tests and inspection. (h) Construction details—cylinder, piston-rods, crosshead, connecting-rod, pins and bearings, shaft and flywheel, governor, valves, frame, foundation, lubricators, and receivers, piping, engine-stop, erection. (i) General: arrangements for delivery into plant.

**213. The only large-size engines in use in electric power plants** are of the Corliss type, and the grid-valve type. The moderate-size, medium-speed or high-speed engine may be of the following types: Corliss, automatic piston valve, or Lents type poppet valve. The high-speed small engine for exciter service or small direct-current generation is practically always a shaft-governor automatic slide-valve or piston-valve engine, generally simple.

Digitized by Google

**214. The medium-power and high-power engines** are practically always compound. Wherever possible, the vertical compound, or at least the angle compound (horizontal-vertical) should be used on account of the saving in floor space, and the more satisfactory wear of the parts. The horizontal engine is used only where the headroom is restricted.

**215. Automatic stops** consist of some form of flyball governor, belt or chain driven from the engine shaft: the governor is so set as to release a trigger or close an electric circuit when the predetermined speed is exceeded. This trigger, or a magnet in the electric circuit, releases a weight arranged to close the throttle. The usual connection consists of a steel wire rope around a drum on the throttle valve stem. In another form of automatic stop the operation of the magnet or trigger releases the pressure of steam on a pilot pipe line; this in turn releasing the pressure behind a piston in the specially designed throttle valve, which then closes. Both the systems are arranged for additional operation by hand.

**216. The operation of steam engines,** after correct adjustment of moving parts has been made, is chiefly a matter of lubrication. In **starting,** the usual procedure is to "crack" the throttle in order to admit a little steam to warm up the engine all over without allowing it to turn. After the preliminary warm-up, standing, the engine is allowed to turn over slowly for a few minutes to warm all parts thoroughly; it is then ready for full speed and load. Five minutes may be long enough for **"warming up"** an engine of 300 h.p. or less; 15 or 20 min. are required for large machines. Just before starting, a few strokes of the hand oil pump (usually attached) should be given, to insure thorough lubrication. All automatic oiling rigs should be started a few minutes before turning over. Drips should be wide open while warming up, and while turning slowly, but closed when the engine is brought up to speed. **Shutting down** only requires the closing of the throttle, shutting off automatic feeds, and the opening of drips. All bolts and nuts should be gone over periodically, say once a month, and a thorough overhauling given the piston, cylinder, bearings, etc., once a year.

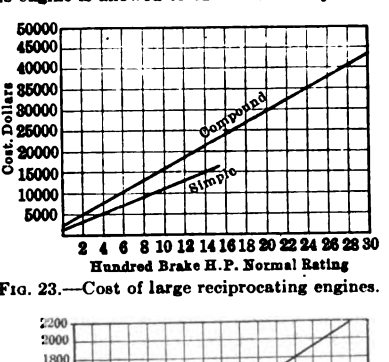

FIG. 23.—Cost of large reciprocating engines.

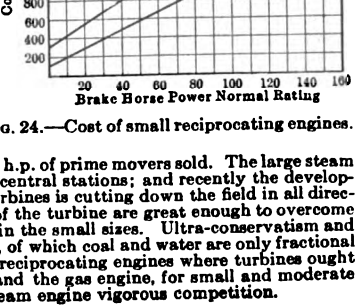

FIG. 24.—Cost of small reciprocating engines.

**217. Engine costs.** Figs. 23 and 24 give the usual costs of large and small engines. The cost per lb. of engine varies from $0.10 to $0.15.

**218. The present status of the reciprocating engine** is revealed by a progressively diminishing percentage of the total h.p. of prime movers sold. The large steam turbine has totally displaced it in central stations; and recently the development of fairly economical small turbines is cutting down the field in all directions. The immense advantages of the turbine are great enough to overcome a slight inferiority in water rate in the small sizes. Ultra-conservatism and ignorance of the real cost of power, of which coal and water are only fractional parts, account for the purchase of reciprocating engines where turbines ought to be installed. The oil engine and the gas engine, for small and moderate sized plants, are also giving the steam engine vigorous competition.

## STEAM TURBINES

**219. The thermodynamics of the steam turbine** is a simpler matter in theory than the steam engine. The energy of the adiabatic expansion in the turbine is converted into kinetic energy by producing motion of the steam particles, which issue from the nozzles as jets.

**220. Resisted and free expansion.** The expansion in the engine is termed "perfectly resisted;" in the turbine it is "free." Therefore all the work is done upon the steam itself during the expansion, producing high velocity of the steam particles; these particles in turn impinge upon curved vanes or buckets, which change the direction of flow of the jets in such a manner as to produce a force in the direction of rotation of the wheel.

**221. The losses** are wholly different from those in the engine; there is no initial condensation, because the parts assume the temperatures of the moving steam, instead of being alternately heated and cooled, and radiation is so slight as to be negligible (0.1 per cent. or less).

**222. Friction.** The only true mechanical friction is in the bearings, and is usually under 2.5 per cent. in small turbines, and under 1 per cent. for larger sizes. The principal loss is steam friction, which is made up of (a) nozzle friction, (b) blade friction, (c) eddies in the flow and (d) windage of the discs or drums revolving in steam. There is some **leakage**, but generally less than in the engine. The presence of any velocity in the exhaust steam is also a source of direct loss.

**223. The flow of gas through a nozzle** is a phenomenon divisible into two classes—(a) above, and (b) below, the critical pressure. When difference of pressure is maintained across an orifice, steam will flow with increasing velocity and in increasing quantity as the pressure difference increases up to that point at which

$$\frac{P_2}{P_1} = 0.58, \text{ for steam,} \tag{38}$$

where $P_1$ = initial pressure in lb. per sq. absolute and $P_2$ = back pressure in lb. per sq. absolute.

**224. The critical pressure is,**

$$P_2 = 0.58 P_1. \tag{39}$$

This is true for all initial pressures. The corresponding velocity varies from 1,300 to 1,500 ft. per sec., and is found practically to coincide with the velocity of sound in steam at the pressure $P_2 = 0.58P_1$.

**225. Effect of reducing back-pressure.** Up to this point (Par. **223**) the stream issues from the orifice in parallel lines; but if the value of $P_2$ is reduced below $0.58P_1$, no further increase in velocity or quantity can be obtained, at the orifice, but there is further acceleration beyond the orifice, and the stream flows out laterally as well as forward. Heavy accoustic vibrations occur, and the efficiency of conversion decreases. To correct this, a conical or conoidal section is added to the orifice, diverging in the direction of flow, and the further pressure drop is permitted to take place in this flaring or trumpet-like exit.

**226. The exit area** should be that suited to the velocity and volume resulting from the total heat drop from the pressure $P_1$ to $P_2$; but the throat always remains of that size required for a pressure of $0.58P_1$, and a velocity of about 1,300 to 1,500 ft. per sec. The theoretical velocities are not realised, due to friction of the steam in the nozzle.

**227. The velocity efficiency of a convergent nozzle** (orifices with rounded entrance) varies from 98 per cent. at low velocities down to 95 per cent. at 1,300 to 1,400 ft. per sec. The **velocity efficiency of a divergent nozzle**, for expansion beyond the critical pressure, ranges from 94 per cent. at 1,500 ft. per sec. to 90 per cent. or 85 per cent. at 3,000 ft. per sec.

**228. The velocity efficiency of the buckets** varies from about 95 per cent. to 98 per cent., for the low velocities used in reaction turbines (less than 1,000 ft. per sec.), to 84 per cent. or 86 per cent. in impulse turbines at velocities of about 2,500 ft. per sec. The second and succeeding rows of buckets or guides in velocity-compounded turbines have even lower efficiencies, reaching 84 per cent. at about 1,500 ft. per sec.

Digitized by Google

**229. The velocity obtainable by expansion** is expressible by

$$V = 223.7\sqrt{H_1 - H_2} \qquad (40)$$

where $V$ = velocity at exit of nozzle in ft. per sec., $H_1$ = total heat contents of steam at initial condition, and $H_2$ = total heat contents of steam at final condition. If $H_2$ denotes the heat contents after an adiabatic expansion, it follows that $V$ is the theoretical value; but $H_2$ is always higher than this, because internal friction reduces the quantity of heat removed from the steam by the work done.

**230. Pressure drop.** In the impulse turbine, all pressure drop occurs in stationary nozzles, and there is no difference of pressure across the moving blades. In the reaction type, about half the pressure drop takes place in the stationary blades, and the remainder in the running blades; and the latter, therefore, act also as nozzles. There is an unbalanced force due to this difference of pressure across the moving blades that must be cared for by balancing devices.

**231. There are two basic types of turbines: impulse and reaction.** Neither of the two is really pure impulse or pure reaction, but the work done by impulse predominates in the impulse type, and the work by reaction in the reaction type. The simple impulse wheel is only employed in the single-stage de Laval type; velocity compounding and pressure compounding are employed in all other impulse types. Compounding becomes a necessity, to secure reasonable rotative speeds.

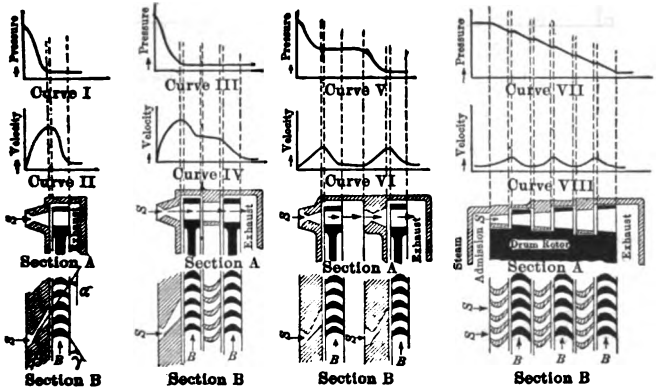

FIG. 25.—Elemental turbine types.*

**232. The steam velocity in a single expansion** from 150 lb. gage to a 28-in. vacuum would be about 3,100 ft. per sec. For best efficiency the blade velocity should be a little less than half the steam velocity, or in this case 1,500 ft. per sec., which results in centrifugal stresses in the disc much in excess of suitable stresses for commercial materials. If the wheel is run slower, the exit velocity of the issuing steam is increased, reducing the efficiency.

**233. In velocity compounding** the exit velocity from the first wheel is received in a series of guide blades and redirected to a second wheel, so that more of the energy is removed, without unreasonable wheel velocities (300 to 600 ft. per sec.).

**234. Pressure compounding** is the division of the pressure drop into two or more stages, which are essentially de Laval single-stage nozzles and wheels in series. Fig. 25 shows these types with characteristic figures.

* From "The Steam Turbine" by J. A. Moyer.

Digitized by Google

**235. The reaction turbine** for best efficiency runs at $\sqrt{2}$ or 1.414 times the peripheral speed of the impulse turbine for the same pressure drop. It is never built single-stage, but always pressure-stage compound.

**236. Principal types.** The de Laval is the original single-stage impulse type; the velocity-compounded type (generally also combined with few-stage pressure compounding as well) is usually known as the Curtis; the pressure-stage type (pure), as the Rateau; and the reaction type, as the Parsons.

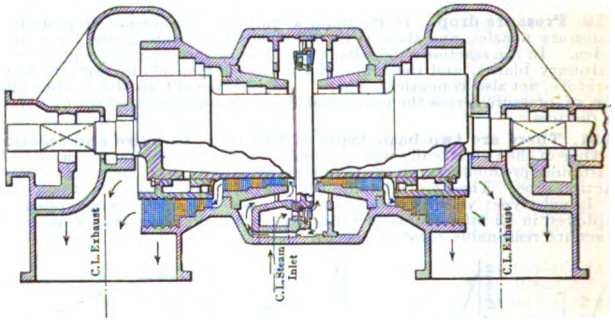

FIG. 26.—Curtis-Parsons double-flow turbines.

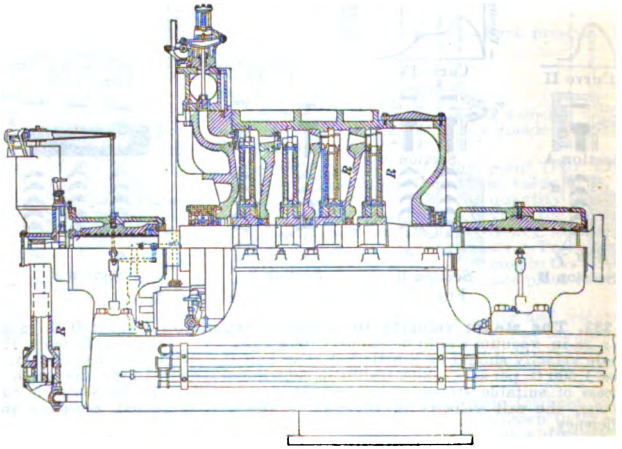

FIG. 27.—Curtis turbine.

**237. The blading** of the three principal types, Parsons, Curtis and Rateau, is shown in Figs. 26, 27, and 28.

**238. Hybrid types** have lately proved the most efficient, or cheaper to build. In moderate sizes the Parsons turbine is built with a Curtis 2-wheel velocity stage for the high-pressure stage; the advantage is a large pressure drop in a small nozzle chamber, avoiding high pressure in the casing, shorten-

Digitized by Google

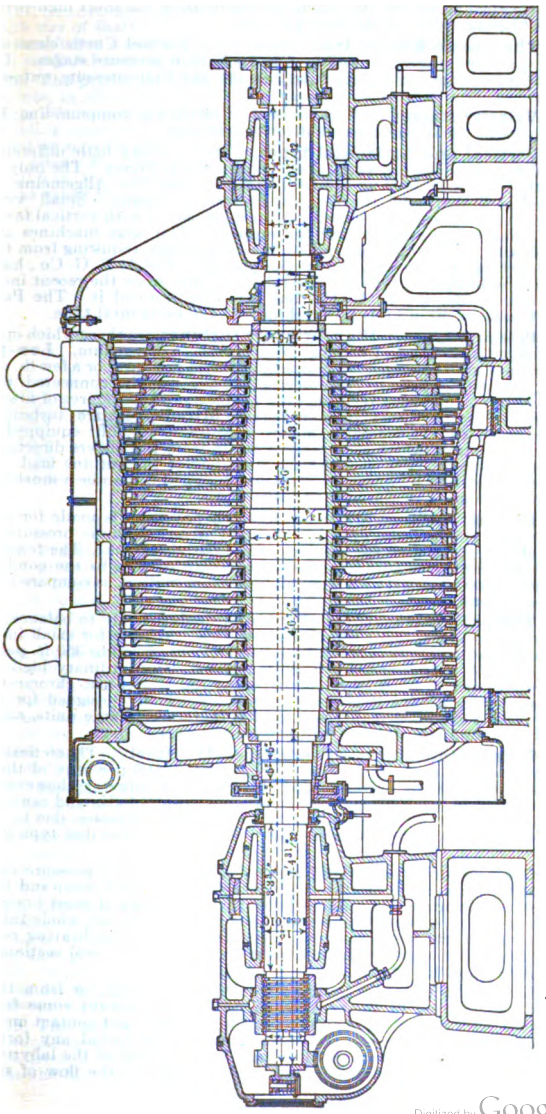

FIG. 28.—Rateau turbine.

Digitized by Google

ing and cheapening the construction, and eliminating the short high-pressure reaction blading, which is the least efficient.

**239. The Curtis-Rateau type** consists of a 2-wheel Curtis element for the high-pressure stage, followed by 6 to 12 Rateau pressure stages. It has the same advantage with regard to keeping the high-pressure out of the casing.

**240. Velocity staging** is the least efficient method of compounding, but is chiefly used for small turbines, as it lowers the cost.

**241. Vertical and horizontal types.** There is very little difference in principal features between vertical and horizontal turbines. The only companies that have built large vertical machines are the Allgemeine Elektricitäts Gesellschaft and the General Electric Company. Small vertical turbines, in small sizes, are sometimes built for use all with vertical fans and pumps, using a ball step bearing for support. The large machines are all provided with oil or water high-pressure step bearings, requiring from 650 to 1,000 lb. per sq. in. pressure, and special pumps. The A. E. G. Co., has discontinued building this type for several years, and since the recent increase in rotative speeds, the G. E. Co. has also discontinued it. The Parsons turbine has never been built in anything but the horizontal type.

**242. Pressure types. High-pressure turbines** are those which operate on full boiler pressure and exhaust to atmosphere or vacuum. **Low-pressure** turbines are those operating on atmospheric pressure, or a few lb. above it, and exhausting into a vacuum. They are usually connected to the exhaust of non-condensing reciprocating engines, or other source of low-pressure steam (except direct from boilers). **Mixed-pressure** turbines are those designed to run normally on low-pressure steam, but equipped with high-pressure stages which may receive steam from the boilers direct, if the low-pressure supply fails to equal the demands of the turbine load. This type is characterized by a low-pressure end designed to handle a much larger quantity of steam than the high-pressure end.

**243. Bleeder turbines** are those in which provision is made for taking steam from a stage of the machine normally at atmospheric pressure, or a few lb. above, to be used for heating, or industrial service. The remainder not so used continues through the low-pressure section to the condenser. This type is characterized by a large high-pressure section, as compared to the low-pressure end.

**244. The principal features of turbine design** relate to balance, leakage, and resistance to high centrifugal stresses. Wheels for small impulse turbines are normally operated at peripheral speeds of 250 to 350 ft. per sec., and 400 to 550 ft. per sec. for large machines, using ordinary high-grade open-hearth steels. For higher speeds up to 700 ft. per sec. chrome-nickel forged steels are used. Reaction turbines are usually designed for much lower speeds, 150 to 350 ft. per sec., or 400 ft. for very large units, and are generally of drum construction, of open-hearth steel.

**245. Speed limitations of open-hearth steel.** Theoretically, a properly designed disc can be run at from 125 to 160 per cent. of the safe speed of a drum with corresponding blading. In practice, however, the difference due to computable tensile stresses from blades and centrifugal force is less important than the unknown harmonic stresses due to blade and disc vibration, and the drum type is better than the disc type in this respect.

**246. Casings for superheated steam** above the 50-lb. pressure section of the turbine are made of cast steel; below this, of cast iron; and for all pressures in saturated steam, of cast iron. The casings of most horizontal turbines are split, so that lifting the upper half exposes the whole interior. With one more lift, the whole rotor may be removed, facilitating repairs to all parts. The vertical turbines must be opened in several sections and taken apart wheel by wheel.

**247. Glands to prevent leakage** from stage to stage, or from the interior of the turbine to the outside air, are nearly always some form of **labyrinth**, with no actual contacts, or at most very light contact on floating rings. The high speeds and lack of lubrication forbid any forms of soft packing except for very small units. The function of the labyrinth is to interpose a large number of constricted passages to the flow of steam.

Digitized by Google

These constrictions usually measure from 0.003 in. to 0.035 in., depending on the size of shaft or dummy ring, and the pressure difference. The clearance is selected according to the vibration at the point of application and is often made a function of the diameter.

**248. The principal blade fastenings** consist of the dovetail for impulse elements, in all sorts of forms from square T-heads to bulb heads with all corners eliminated; the reaction blading of Parsons make is a caulked type, depending upon some distortion and friction for the grip. Riveted blading is used to some extent in small impulse turbines, but has been a failure in large discs. Fig. 29 shows three sucessful types. **Blade heights** vary from 0.5 in. to 18 in., depending on the size of the machine, and the stage. Widths range from 0.25 in. to 2 in.

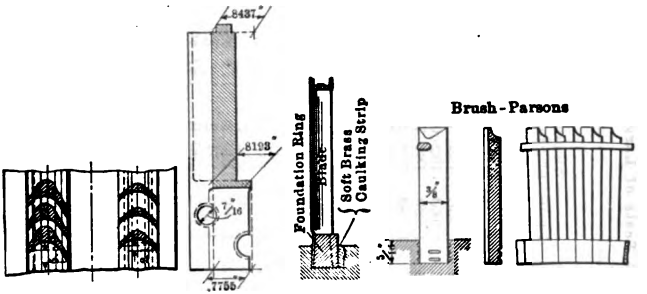

FIG. 29.—Four types of blade fastenings.

**249. Pressure stages.** In high-pressure Curtis turbines, the usual number of pressure stages is five to seven, with two velocity stages in each pressure stage. In Rateau types, there are about thirteen to twenty-two pressure stages, with one wheel in each; or one Curtis stage of two velocity stages may take the place of two or three high-pressure stages. The Parsons type has from forty to seventy pressure stages.

**250. Turbine rating.** Impulse turbines are rated on a basis of calculated flow through the nozzles and known efficiencies of different types of wheels. Thus a wheel of given size may be of widely varying horse-power under different areas of nozzles; the efficiencies also are altered. Reaction turbines must be designed for the load, and can only be altered in best load capacity by increasing the initial pressure. Overload is provided for in the impulse type by adding extra nozzles; in the reaction type by by-passing some of the high-pressure stages.

**251. Measurement of shaft output.** The output of the turbine must be obtained by brake, or electrically; no indicated horse-power exists; in small turbines, throttle governed, the steam-chest pressure bears an accurate relation to the horse-power delivered at any speed, and if the turbine is calibrated, it may be used as an indication of the output thereafter. This is true because the pressure is a measure of the steam flow, and the steam flow is a measure of the output, for any given turbine efficiency.

**252. Lubrication is exceedingly simple.** No internal oiling whatever is employed; gravity or force feed with copious supply at 15 to 25 lb. pressure is general for large units. The speed of rotation causes a dragging of oil under the journal, by means of viscosity, so that the journal never rides on metal. Some turbines actually rise a few thousandths of an inch after coming to speed due to increase in the oil film under the journal. Small turbines are ring-oiled like motors.

**253. The actual Rankine-cycle efficiency ratios** obtained in small non-condensing turbines vary from 45 per cent. to 50 per cent., for large units, from 55 to 65 per cent. for the great majority, up to 71 per cent. as about the highest. These figures assume condensing service in each case.

This table gives efficiency ratios and B.t.u. per kw-hr. The latter figure is obtained from the water rate and the steam conditions.

$$\text{B.t.u. per kw-hr.} = W \times (H_1 - q_3) \qquad (41)$$

Where $H_1$ = heat contents of steam supplied to turbine, q = heat of the liquid in condensate and $W$ = water rate in lb. per kw-hr.

The thermal efficiency is the product of the efficiency ratio and the thermal efficiency of the Rankine cycle (adiabatic expansion).

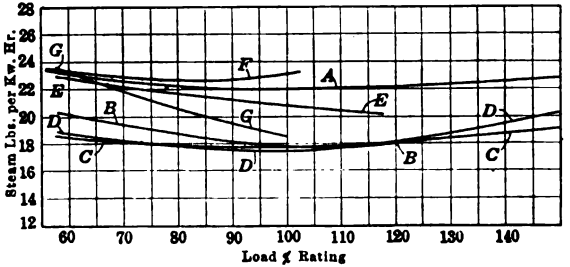

FIG. 30.—Water-rate curves of small condensing turbines, steam, 150 lb. gage; superheat, 100 deg. Fahr.; vacuum, 28 in.

*A*, 250 kw. Westinghouse, 3,600 r.p.m.; *B*, 400 kw. Westinghouse, 3,600 r.p.m.; *C*, 500 kw. Westinghouse, 3,600 r.p.m.; *D*, 1,000 kw. Westinghouse, 1,800 r.p.m.; *E*, 200 kw. DeLaval; *F*, 400 kw. Kerr, 1,500 r.p.m.; *G*, 1,000 kw. Rateau.

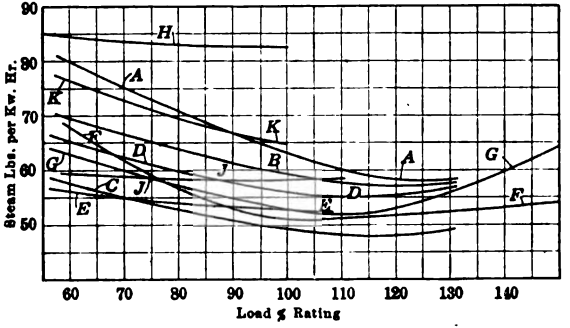

FIG. 31.—Water-rate curves of small non-condensing turbines with dry steam at 100 lb. gage.

*A*, 35 kw. Curtis, 3,600 r.p.m.; *B*, 75 kw. Curtis, 3,300 r.p.m.; *C*, 100 kw. Curtis, 3,600 r.p.m.; *D*, 125 kw. Curtis, 2,400 r.p.m.; *E*, 300 kw. Curtis, 1,800 r.p.m.; *F*, 250 kw. Westinghouse, 3,600 r.p.m.; *G*, 300 Westinghouse, 3,600 r.p.m.; *H*, 50 kw. Sturtevant, 1,400 r.p.m.; *J*, 150 kw. Sturtevant, 2,100 r.p.m.; *K*, 50 kw. Terry, 2,800 r.p.m.

**255. Water-rate curves.** Figs. 30, 31, and 32 give characteristic water-rate curves for small and large units. It is found that the **Willans line** (total steam per hour vs. output) is practically straight line from zero load to full (or best) load; on overload, with by-pass, or extra nozzles open, it is usually another straight line, joining the first at best load, but more steeply inclined. This property allows fractional-load water rates to be readily interpolated from one or two load tests or guarantees.

**256. The effect of variation in vacuum** on a turbine differs somewhat with the type of machine, but can be obtained with reasonable accuracy from Fig. 33, which gives average figures for high-pressure turbines; Fig. 34 applies to low-pressure turbines. A vacuum of 28 in. is taken as the standard for high-pressure, and 27.5 in. for low-pressure units.

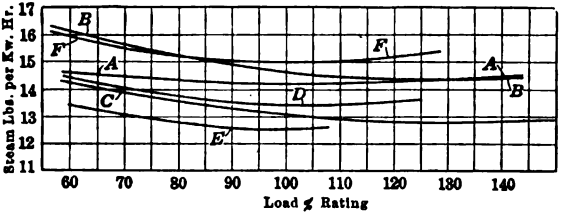

FIG. 32.—Water-rate curves of large condensing turbines. Steam, 200 lb. gage; superheat, 100 deg. Fahr.; vacuum, 28 in.

*A*, 9,000 kw. Curtis; *B*, 10,000 kw. Curtis; *C*, 4,000 kw. Curtis-Rateau; *D*, 10,000 kw. Westinghouse; *E*, 6,000 kw. Parsons; *F*, 6,000 kw. Zoelly.

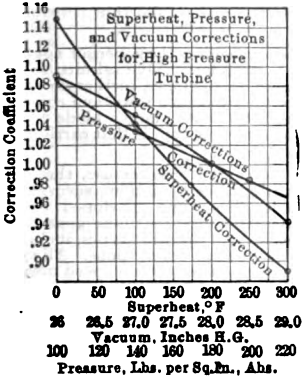

FIG. 33.—Superheater pressure and vacuum corrections for high-pressure turbines.

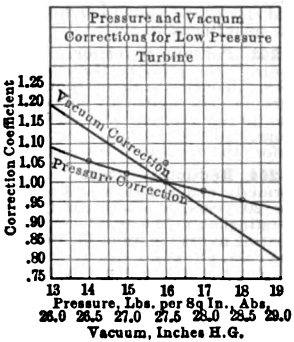

FIG. 34.—Pressure and vacuum corrections for low-pressure turbines.

**257. The effect of superheat** in improving economy is usually taken at the rate of 10 per cent. for the first 100 deg. of superheat, 8 per cent. for the next 100 deg., and 7 per cent. for the third hundred. Figs. 33 and 34 show the corrections, which are practically identical for all types.

**258. The efficiency losses** may be subdivided into (a) nozzle friction, 6 to 28 per cent.; (b) blade friction, 6 to 30 per cent. (c) windage, 3 to 15 per cent.; (d) unused exit velocity, 3 to 5 per cent.; (e) leakage 2 to 10 per cent.; (f) mechanical losses, 1 per cent. As all the steam losses in the high-pressure stages reappear in the steam as unused heat, the available heat drop is increased by translation of the expansion lines to higher entropies, as shown by the **Mollier diagram,*** hence the whole turbine-diagram efficiency in a multi-stage turbine is always from 2 to 6 per cent. higher than that of the individual stages.

* Marks & Davis "Steam Tables," Longmans, Green & Co., N. Y., 1912.

Digitized by Google

**259. The efficiency of the turbine,** though different for different speeds and pressures, does not change appreciably with time or service. The shaft horse-power or brake horse-power is from 3 to 15 per cent. less than the calculated diagram horse-power (corresponding to i.h.p. in the engine). The usual friction losses are generally less than one-half those of steam engines of the same rating. **Mechanical friction** in the turbine is confined to bearings and governor drive; it is usually under 1 per cent., and in large machines is less than 0.5 per cent. Internal or steam friction is caused by imperfect shape of blades, and windage of the discs or drums.

**260. Pressure correction,** for variations in steam pressure from guaranteed or desired conditions, is given in Fig. 33 and 34 for high-pressure and low-pressure turbines. The correction is the same for all types.

**261. Governors for turbine speed regulation** are always of the centrifugal type; the inertia governor cannot be employed, because there can be no sudden angular accelerations. The centrifugal governor can be made nearly isochronous; generally, however, there is a slight decrease in speed as load increases.

**262. Throttling governors.** For all small turbines (impulse type) and some large makes, the plain throttling governor is employed, simply controlling the admission pressure at the steam chest or first stage. The old Parsons governor for reaction turbines admitted steam at full pressure, in short puffs, lengthening the period the valve was open as the load increased. Many of the Curtis types are governed by multiple-nozzle control, opening and closing individual nozzles, from 6 to 16 in number, and thus controlling the quantity of steam.

**263. Parsons governor.** In the Parsons machine, the governor not only controls the primary throttle, but also a secondary valve admitting live steam in one-sixth to one-fourth the total number of stages, further down the turbine. This virtually cuts out of service the by-passed rows, and converts the turbine into one of fewer stages, but in effect having larger blade dimensions, and not as economical. The best load for this type is that carried just before the opening of the secondary valve.

**264. Reduction gears** have recently come into greater use, than was formerly made of them. The de Laval turbine has used them successfully for 20 years, at enormous relative speeds. The type developed by the Westinghouse Machine Company from the Melville-Macalpine gear has a floating hydraulic frame for aligning the gears. All the other types, including the Falk, Fawcus, Parsons, etc., use solid bearings and connections. All types employ the double helical gear. By this means the turbine speed may be kept high, for economy both in cost and steam, and the driven apparatus may be operated at comparatively low speed. Direct-current generators, fans, and centrifugal pumps for large volume and low speed, may thus be successfully combined with the turbine with good economy.

**265. Turbine specifications** should cover the following items: (a) Number of units and location; character of building. (b) Service, and attachment to driven apparatus (direct, flexible coupling, reduction gear, etc.) (c) Speed, steam and back pressure conditions. (d) Capacity, overload, electric system data. (e) Regulation, variation of speed under change of load. (f) Noise, vibration. (g) Tests and inspection. (h) Mechanical details of connection to driven apparatus. (i) Type and steam system, H. P., L. P., bleeder mixed pressure, giving quantities for L. P., or bleeding steam. (j) Materials—casing, wheels, nozzles, blades, shaft. (k) Piping connections. (l) Bearings. (m) Foundations. (n) Oiling. (o) Auxiliary apparatus—oil pumps, relays, step-bearing pumps (for vertical turbines.) (p) Painting and lagging. (q) Gages and miscellaneous equipment.

**266. Turbine supports** should always be carefully designed to prevent distortion of the parts; stiffness of the supports is usually very desirable, but great mass is unnecessary; many reaction turbines of large size are running on foundations entirely of steelwork, which is low in mass for the strength and stiffness.

**267. The auxiliaries required for horizontal turbines** consist only of an **oil pump,** for large self-contained units: no auxiliaries whatever are needed for small units.

Digitized by Google

**268. The auxiliaries for vertical units** include in addition to the oil pump, **step-bearing pumps** for oil or water, capable of handling pressures of 500 to 1,000 lb. per sq. in. (varying with the size of the main unit). These step-bearing pumps, with the piping, are generally in duplicate. In order to steady the oil supply, a frictional resistance called a **baffler** is employed between pump and step bearing; and to remove pulsations of pressure and provide a small reservoir, **accumulators** of the elevator type are also required.

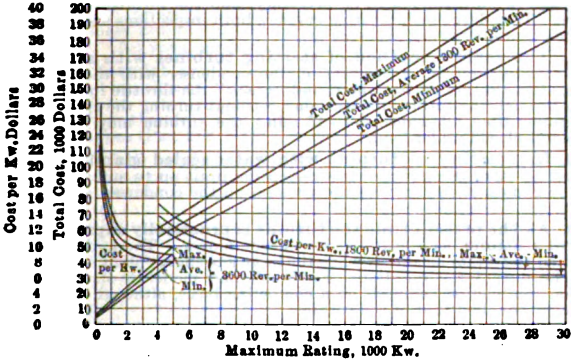

FIG. 35.—Steam turbines. Cost per kw. *vs.* capacity. Total cost *vs.* capacity.

60 Cycles, maximum 24 hr. rating, 50 deg. Cent. rise; power factor, 80 per cent.; pressure 175 lb.; superheat, 100 deg. Fahr.; vacuum, 28.5 in.

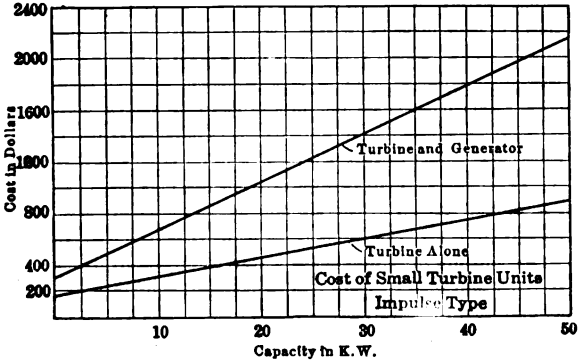

FIG. 36.—Cost of small turbines and generators.

**269. The cost of turbines per kw.**, including generators, varies from $30 for small sizes down to $9 or less for very large units, at normal rating; or at maximum rating, $10. Fig. 35 gives the cost per kw. (normal rating) of large units including generators; Fig. 36 gives the cost per h.p. of small turbines with and without generators.

Digitized by Google

**270. The operation of the steam turbine** is remarkable for its simplicity; one oiler can attend to two or three units (on the engine-room floor) aggregating as much as 40,000 or 50,000 kw. But with engines, only 3,000 or 4,000 kw. can be cared for by one man; and in many cases much less. The turbine is practically undamaged by priming which would wreck an engine, and has a maintenance cost but one-fifth as great, approximately. There are very few articulated parts in the turbine; its continuous operation is therefore much more reliable and periods of two to four weeks continuous operation are common. **Inspections** made once a year frequently show no repairs or adjustments to be necessary, and the turbine is continued in service. With large reciprocating engines, both inspections and adjustments are sometimes necessary every 24 hr.

**271. The general method of starting turbines with steam-sealed glands** is to establish a vacuum on the condenser with the dry-vacuum pump, start the circulating water, and "crack" the throttle in order to send steam through the turbine for warming, without turning the spindle. After the proper time allowance (5 to 15 min.) the turbine may be brought to speed and placed under load.

**272. In starting a turbine with water-sealed glands**, it is usual practice to start the turbine non-condensing until up to sufficient speed to seal the glands, then establish the vacuum on the condenser and apply the load.

**273. At the present time the turbine is practically supreme in large central stations**, as a heat-operated prime mover. The hydraulic station is limited to certain localities, while the large gas-engine plant is so unreliable as to be out of the question. For small and moderate-sized plants the internal-combustion engine is on a competing basis, although its reliability has never equalled that of the turbine.

**274. The field for small steam turbines** is readily increasing, particularly since centrifugal boiler-feed pumps, circulating-water pumps, fans, blowers, etc., are successfully designed for turbine speeds, with good efficiencies. The small amount of attention required by the turbine, its reliability and low maintenance are generally more than sufficient to overbalance a slight inferiority to the steam engine in economy. **Since the item of fuel economy is only one of the factors in operating cost**, this result is natural and the use of the turbine is bound to increase. There is yet much to improve in the turbine, whereas the reciprocating engine has been at a virtual standstill in development for 10 years past.

## CONDENSING EQUIPMENT

**275. Thermodynamics of condensers.** The heat given up by the condensing steam must equal the heat received by the circulating water. In jet or barometric condensers, the steam and water mix; no difference between the temperature corresponding to the vacuum and the temperature of the discharge water need exist. The surface condenser requires some difference of temperature between the steam and the circulating water at all times, or no heat flow from steam to water can take place.

**276. Removal of air.** The air present in the condensate is chiefly drawn in by leakage at the joints. This air, being non-condensible, must be removed by segregation and pumping.

**277. The volume of condensate water** is practically negligible compared with the steam volume at the same pressure. The **work in ft-lb made available by the condenser** is the steam volume multiplied by the pressure difference in lb. per sq. ft. existing between the atmosphere and the interior of the condenser; the work required to produce this effect, is merely the product of the number of cu. ft. of condensate and the same pressure difference. At 28 in. vacuum the ratio of these two is 21,000 to 1. To the **condensate pump work** must be added the **work of the circulating-water pump** (chiefly a friction loss) and the **work of the dry-vacuum pump** which removes the air.

**278. The principal condenser types** are: (a) jet; (b) barometric; (c) eductor or siphon; (d) rotary jet; and (e) surface. These are described in Par. **279** to **283.**

Digitized by Google

**279. The jet condenser consists** of a cast-iron shell into which the exhaust pipe is led, having the circulating water sprayed through the chamber in jets. The steam condenses and mingles with the jets, and is pumped out of the bottom of the shell. **The barometric condenser** is a jet condenser set higher than 34 ft. above the level of the discharge well or tunnel; the water therefore runs away by gravity, but must be pumped in, due to a slight friction loss and velocity head, the vacuum assisting the circulating pump.

**280. In the eductor or siphon type,** the injection water is pumped in under 25 to 30 lb. pressure, and requires sufficient velocity to carry out not only its own mass but the condensed steam and entrained air as well, by kinetic energy. No vacuum pumps are required.

**281. The rotary jet types**—originally developed by Le Blanc—consist of a centrifugal impeller throwing segments of water into a nozzle, in such fashion as to form water pistons, which trap and condense the steam, and push before them the air. This type is also used as a dry-vacuum pump. All the above types (Par. 279 to 281) are derivatives of the true jet condenser.

**282. The surface condenser** consists of a cast-iron shell with two heads or water boxes into one of which the circulating water passes. These two boxes are connected by a large number of small brass tubes, which allow the circulating water to traverse the main shell without contact with the steam; the latter is fed into the shell around the tubes. The circulating water passes to the second box, which may lead to the discharge or redirect the water back to another section of the first box by way of another nest of tubes. If the first type is used it is called **single pass**; if the second, **two pass**; and so on, with three or four passes in some few cases. The cold water passing through the tubes condenses the steam by conduction, and the condensate trickles down to the bottom of the shell, there to be pumped out. The air, which is always heavier than steam at the same temperature, also collects at the bottom and must be pumped out, preferably by another pump.

**283. Atmospheric condensers** consist of a form of surface condenser in which the cooling medium is a mixture of air blast and water spray. The air takes up some of the spray, becoming cooled thereby, and acts as a cooling medium for the steam. High vacuum is not to be obtained with this type. The chief feature is economy of circulating water, which may be in the ratio of 1 lb. of water per lb. of steam, or slightly less, since the whole latent heat of evaporation (of the water spray) as well as the heat of the liquid is available for cooling.

**284. Quantity of circulating water required.** In the jet or ordinary surface types, the circulating water must be at least 25 to 30 times the weight of the steam condensed. In the jet condenser, the condensate mixes with the circulating water, and, if the latter is dirty, is necessarily lost. The surface condenser keeps the condensate separate from the circulating water, so that it is available for re-use in the boilers, a pure distilled water (Par. 137 and 138).

**285. The proportions of jet condensers** are relatively unimportant, the design merely providing for adequate mixture of water and steam. The shell therefore need only be large enough to take the exhaust and water connections. The volume of a jet condenser varies from 0.5 to 2.5 times the volume of the low-pressure cylinder volume of a reciprocating engine; in the eductor types, the volume is somewhat less.

**286. Surface condensers are limited in capacity by the rate of heat transfer.** For average practice, 300 to 350 B.t.u. per sq. ft. per degree mean temperature difference per hour can be allowed. It follows from this assumption that

$$A = W \times \frac{(H_2 - q_3)}{U \times t_m} \qquad (42)$$

where $A$ = area in sq. ft. of tube surface, $W$ = lb. of steam per hour from exhaust, $H_2$ = total heat per lb. of exhaust, $q_3$ = heat of the liquid per lb. (at condensate temperature), $H_2 - q_3$ = 1,000 to 1,050 for most cases, $U$ = transmission coefficient = 300 to 350 B.t.u. per hour, per sq. ft., per degree mean temp. difference (Fig. 37), and $t_m$ = mean temperature differ-

Digitized by Google

ence between steam and circulating water. The arithmetic formula for $t_m$ is:

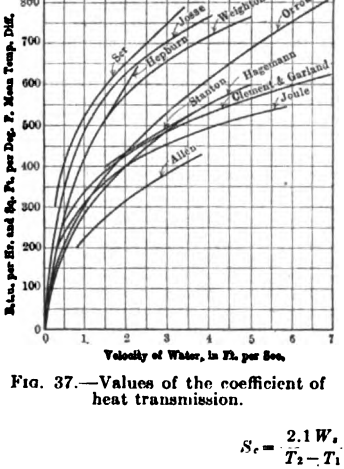

FIG. 37.—Values of the coefficient of heat transmission.

$$t_m = T_0 - \frac{(T_1+T_2)}{2} \qquad (43)$$

where $T_0$ = steam temperature at the vacuum, $T_1$ = injection temperature and $T_2$ = discharge temperature. The logarithmic formula for $t_m$ is:

$$t_m = \frac{T_2 - T_1}{\log_e\left(\frac{T_0 - T_1}{T_0 - T_2}\right)} \qquad (44)$$

For the majority of cases, Eq. 43 is sufficient.

**287. The quantity of circulating water required for jet condensers** is given by

$$W_c = \frac{H_2 - T_1 + 32}{T_2 - T_1} \qquad (45)$$

where $Wc$ = lb. of circulating water per lb. of steam, $H_2$ = heat contents per lb. of steam, $T_2$ = discharge temperature, and $T_1$ = injection temperature. The quantity required in gal. per min., taking $H - T_1 + 32$ as 1050 B.t.u., is

$$S_c = \frac{2.1\,W_s}{T_2 - T_1} \qquad (46)$$

where $W_s$ = lb. of steam per hour, and $S_c$ = circulating water in gal. per min.

**288. Examples of Modern Condenser Proportions**

| Name of station | Size of turbo-generators on max. 24-hr. rating | Sq. ft., total | Sq. ft., per kw. |
|---|---|---|---|
| Commonwealth Edison Co. | | | |
| Northwest Station | 20,000 kw. | 32,000 | 1.60 |
| Quarry St. | 14,000 | 25,000 | 1.79 |
| Fisk St. | 12,000 | 25,000 | 2.08 |
| Interborough R. T. Co. | | | |
| 59th St. Power Station, N. Y., (Engine and low-pressure turbine.) | 15,000 | 25,000 | 1.67 |
| 74th St. Station | 30,000 | 50,000 | 1.67 |
| Metropolitan St. Ry., Kansas Cy. | 10,000 | 22,000 | 2.20 |
| Marion Station, P.S.E. Co., N. J. | 18,000 | 25,000 | 1.39 |
| United El. Lt. & Power Co., N. Y. | 15,000 | 25,000 | 1.67 |

**289. The quantity of circulating water required for surface condensers** is

$$W_c = \frac{H_2 - T_3 + 32}{T_2 - T_1} \qquad (47)$$

where $T_3$ = condensate temperature, and the other symbols have the same significance as before. For jet condensers $T_3$ becomes $T_2$; for surface condensers $T_3$ is at least 5 deg. Fahr. higher than $T_2$, and generally 10 or 15 deg. higher.

**290. Use of dirty condensing water.** For jet condensers, very dirty circulating water may be used, except that if sewage or other gas-producing

Digitized by Google

matter is contained, the work of the dry air pump will be greatly increased. Dirty water in surface condensers causes slime deposits on the tubes, if containing grease and sewage; or it incrusts the tubes with scale, if very hard. In either case, periodic cleaning is necessary, as both deposits lower the efficiency of heat transmission.

**291. Screens** are usually made of iron mesh or bars, with openings the same size as condenser tubes or ¼ in. smaller; these screens are set in frames, and operate in slides for cleaning purposes. Small metal screens enclosed in cast-iron boxes in the suction pipe are employed for small sizes and are then usually called "fish-traps." A later development is the use of moving self-cleaning screens, either arranged drum fashion like a stone screen, or like a chain grate set on edge. **The velocity through screens** should not exceed 4 to 5 ft. per sec.

**292. Pumps. Circulating-water pumps** in modern plants are always centrifugal or propeller types, especially since the advance of the small steam turbine. **Wet vacuum pumps** handle both condensate and non-condensible gases. They are not used to any extent at present. **Dry vacuum pumps** handle non-condensible gases only. Condensate or **hot-well pumps** handle the condensate only. The separate pumps are much more efficient than the combined wet-vacuum pump. The hot well-pump is usually a one-stage or two-stage centrifugal. The dry-vacuum pump may be a reciprocating compressor specia ly designed for tightness and small clearance, or a hydraulic device using a form of centrifugal pump and water jets to entrain the air, such as the Le Blanc pump.

**293. Power required for auxiliaries.** The circulating pump, if a reciprocating dry-vacuum pump is used, requires 85 per cent. to 90 per cent. of the total h.p. for condenser auxiliaries; the condensate and dry-vacuum pumps, 5 to 7 per cent. each. The total h.p. at 27 in. to 28 in. vacuum is about 2 to 2½ per cent. of the main unit, for reciprocating main engine; 3 to 3.5 per cent. at 28 to 29 in. vacuum for turbine plants.

**294. The steam demand of all condenser auxiliaries,** using engine-driven circulator, is 3 to 5 per cent. of the total; for direct turbine-driven circulator, 5 to 9 per cent.; for latest type geared turbine-driven circulator, 4 to 6 per cent. The water rate of turbines used for hot-well pumps is 50 to 60 lb. per b.h.p.-hr.; for low-speed direct-connected turbines for circulators, 35 to 45 lb.; for geared high-speed turbines, 29 to 35 lb.

**295. Recent High Vacuum Results with Large Surface Condensers**

| Plant | Surface, sq. ft. | Water per lb., hr. | Hot well temp., deg fahr. | Circ. water In deg. fahr. | Circ. water Out deg. fahr. | Vacuum 30-in. Bar. | Ratio sq. ft. kw. |

**296. Hydraulic dry-vacuum pumps** take from 6 to 12 times as much power as the reciprocating types; but this is relatively unimportant if the exhaust steam is usable in the feed-water heaters.

FIG. 38.—Vacuums and circulating-water temperatures.

**297. The obtainable vacuum** (Fig. 38) depends chiefly upon the temperature of condensing water. The actual results obtained may be less than this due to air leakage or dirty tubes.

Digitized by Google

**298. Cooling towers** are employed where condensing water cannot be obtained in sufficient quantity for complete rejection of discharge. The circulating water is broken up into spray or thin sheets and falls through a current of air. The air in becoming warmer, takes up heat from the water; evaporation also takes place and tends to saturate the air. This **evaporation** is from 0.80 to 0.95 lb. per lb. of steam exhaust to the condensers, exclusive of the spray loss in water actually carried away mechanically in the air current. The distance between spray outlets and tank under the tower is usually about 25 ft. so that this head, plus friction in additional piping, must be added to the total pump head. The towers are 50 ft. to 80 ft. high for natural draft; but may be shorter if a forced draft fan is used, provided the rain from the tower is not objectionable. The ground area required is 1 sq. ft. per 20 lb. steam condensed per hr. approximately. The circulating water required is 60 gal. per sq. ft. of ground area, cooled from 95 deg. to 75 deg., which is average performance. The heat transmission to air per sq. ft. of cooling surface in the lattice work or screens runs from 350 to 850 B.t.u. per hr. The circulating water required is 25 to 30 lb. per sq. ft. per hr. The work of the circulating water pump is practically double that of the ordinary installation without towers, or 6 to 8 per cent. of the h.p. of the main unit. If forced draft is used, the fan requires 0.3 per cent. to 0.5 per cent. of the h.p. of the main unit.

**299. The operation of condensing equipment** becomes very simple with turbine-driven auxiliaries, as these require almost no attention. Depending on the water, condenser tubes should be cleaned from once a week to once a month; brushing the tubes may be necessary. All joints should be very carefully made and maintained tight; shellacing or painting is of great assistance in this respect. The ferrules of the tube ends need taking up from time to time, as the packing shrinks, or as the vibration loosens the ferrules.

**300. Starting.** The circulator should always be started first, so as to keep the tubes cool at all times when steam may come in contact with them; as soon as the circulator is running, the main unit may be started, and the hot-well pump. Whenever the vacuum is desired, the vacuum breaker valve may be closed and the dry-vacuum pump started.

**301. Shutting down:** shut off the main unit, break the vacuum with the breaker-valve, shut down the dry air-pump, then the hot-well pump, and lastly, the circulating water pump.

**302. The piping** should be so arranged that air can be removed from the highest point of the circulating water system; otherwise, air might accumulate and prevent water from entering part of the tubes, besides breaking the siphon. The discharge pipe should be submerged in the discharge tunnel or well, so as to have an inverted siphon, not to exceed 25 ft. head; this reduces the circulating pump head to friction and velocity only.

**303. The cost of condensing equipment** complete, including pumps, barometric type, is from \$0.16 to \$0.25 per lb., average \$0.21; cost per kw. of main unit, \$0.90 to \$1.95, average \$1.10 for moderate and large size units. For very small units the cost may go up to \$4.00 or \$5.00 per kw. Jet condensers cost from \$1.35 to \$2.10 per kw., average \$1.65, for moderate and large sizes; \$3.00 to \$4.50 for small units. The figures assume 26 in. or 27 in. vacuum and are based on normal kw. rating. Surface condensers, 28 in. to 29 in. vacuum, cost per kw. of main unit from \$2.25 to \$4.22, average \$3.12; this is based on maximum rating of units and applies to large sizes. Small surface condensers cost from \$3.50 to \$10.00 per kw. Cooling towers, \$3.12 to \$6.00, average \$4.30, per kw. rating of units attached.

## FEED-WATER HEATERS

**304. The heat transfer in closed feed-water heaters** is exactly the same as in surface condensers; that in open heaters, the same as in jet condensers, as covered in Par. **285** to **289**. The feed-water heater is merely a condenser operated at atmospheric pressure, with boiler feed-water for condensing water.

**305. The open heater** is much like a jet condenser in general arrangement, but is usually a rectangular box, or cylindrical tank large enough to

Digitized by Google

provide a little storage capacity for feed water, as the boiler feed pumps usually draw direct from the heater.

**306. The closed heater** is usually built much like a surface condenser and is then known as the straight-tube type. In some makes the tubes are corrugated, in others coiled, or with a single U-bend; or an expansion joint is placed in the shell; in these cases the tubes are expanded fast in the tube sheets.

**307. The water velocities** employed in closed feed-water heaters are usually slower than for surface condenser practice, so that the value of the transmission coefficient is reduced. An average figure is 300 B.t.u. per deg. mean temp. difference per sq. ft. per hr.

**308. The mean temperature difference** given by the arithmetic formula is close enough.

$$t_m = t_s - \left(\frac{t_2 + t_1}{2}\right) \tag{48}$$

where $t_s$ = temperature of exhaust steam at exhaust pressure (usually 212 to 214 deg.), $t_2$ = temperature of heater discharge water, and $t_1$ = temperature of heater inlet water.

**309. Temperature rise.** If a given quantity of exhaust steam is available, the resulting temperature rise in a closed heater may be found as follows:

$$(t_2 - t_1) = \frac{w_s(H_s - q_3)}{W} \tag{49}$$

where $W$ = feed water in lb. per hr., $w_s$ = exhaust steam in lb. per hr., $H_s$ = total heat of exhaust steam per lb. (usually 1,150 B.t.u.), $q_s$ = heat of the liquid (condensed steam), at the temperature leaving the heater ($t_3$), usually 212 deg., $t_1$ = temperature of feed water at heater inlet, and $t_2$ = temperature of feed water at heater discharge. For all ordinary cases, $H_s - q_3 = 970$; $t_2$ cannot be higher than 208 deg. fahr., if exhaust steam at 212 deg. is employed. If the value of $t_2$, as found above, exceeds this, it indicates that there is excess exhaust steam. Eq. 56 can be transposed to solve for $w_s$, if the amount of exhaust steam to heat the feed water to 208 deg. is desired.

**310. Temperatures Obtainable in Open Feed Water Heater**
(Temperature of steam, 212 degrees F.)
Initial Temperature of Feed Water, Degrees F.

| Per cent. of total steam used by auxiliaries. | 40 | 50 | 60 | 70 | 80 | 90 | 100 | 110 | 120 | 130 |

| 10 | 133.3 | 143.1 | 152.3 | 161.4 | 170.6 | 179.8 | 189.0 | 198.1 | 207.3 | 212.0 |
| 11 | 142.5 | 151.6 | 160.7 | 169.7 | 178.9 | 188.2 | 197.0 | 206.2 | 212.0* | 212.0* |
| 12 | 150.9 | 159.9 | 168.9 | 177.9 | 187.0 | 196.0 | 205.0 | 212.0* | 212.0* | 212.0* |

**311. The surface required in closed heaters** is given by

$$A = \frac{W(t_2 - t_1)}{U t_m} \tag{50}$$

where $U = 300$ and $A$ = area of tube surface in sq. ft.; the other symbols are as given in Par. **309**.

**312. Heaters are rated in h.p.** One h.p. equals 30 lb. of exhaust steam per hr.

* All of the steam not condensed.

Digitized by Google

**313. The volume required in open heaters is given by**

$$V = \frac{HP}{a} \tag{51}$$

where $V$ = volume in cu. ft., $a = 2.15$ for muddy water, $a = 6$ for slightly muddy water, and $a = 8$ for clean water.

**314. Operation.** The operation of closed heaters is somewhat more expensive than open heaters; the tube packings require attention and the tubes must be cleaned of scale, if this forms. In heaters with corrugated or bent tubes, cleaning is practically impossible. The advantage of the closed heater is the elimination of oil from the feed water, but with the use of turbine-driven auxiliaries, this advantage disappears, as there is no oil in the exhaust steam. In open heaters, the cast-iron trays over which the feed water spills, are readily removable for cleaning. If an open heater is used on oily exhaust, some means of oil elimination must be used, sometimes supplemented by a filter in the body of the heater.

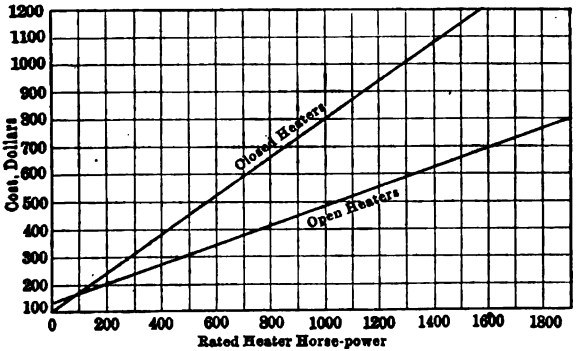

FIG. 39.—Cost of feed-water heaters.

**315. Connection to feed pump.** Closed heaters may be either the suction or the discharge side of the feed pump; open heaters, only on the suction side. Either type when on the suction side of the pump, must be above it.

**316. The cost** of heaters is given in Fig. 39.

## ECONOMIZERS

**317. The laws of heat transfer for economizers** are the same as for surface condensers and closed water heaters. But the substitution of a gas for the steam increases the resistance enormously, and the value of the transmission coefficient is much lower and is very uncertain in value.

**318. Types.** There are two types: the **staggered tube** and the **non-staggered tube.** In both types the tubes are arranged in vertical rows attached to headers at top and bottom of each row, perpendicular to the gas flow. The staggered arrangement serves to break up the gas stream thoroughly. The tubes are always of cast iron and are usually 4½ in. diameter and 10 ft. long.

**319. The surface required** is based on empirical values, because the temperature and quantity of flue gases per lb. of coal, waterflow and condition of surfaces, introduce so many independent variables that the rational formulæ used for condensers and heaters are useless. The surface installed varies from 3 to 5 sq. ft. per rated boiler h.p. connected.

Digitized by Google

**320. The temperature rise** is given by

$$X = \frac{y(T_1 - t_1)}{91 + \frac{5w + GCy}{2GC}} \qquad (52)$$

where $X$ = rise in temperature of feed (deg. Fahr.), $T_1$ = temperature flue gases entering economizer, $t_1$ = temperature feed water entering economizer, $w$ = lb. of feed water per boiler h.p. per hr., $G$ = lb. flue gas per lb. of combustible (average, 20), $C$ = lb. of coal per boiler h.p. per hr., and $y$ = sq. ft. of economiser surface per boiler h.p. A rough method, if the temperature drop of flue gases is known, is to take 0.5 deg. rise in feed water for every deg. drop in flue gases.

**321. The feed water enters** the bottom headers by a connecting main and is collected from the top headers by another main, placed at the opposite end of the headers, so that the tubes form equal parallel paths.

**322. The draft loss** through economizers varies with the velocity of the gases, as in the boiler. At normal full load on the connected boilers the loss is from 0.25 in. to 0.40 in. (of water), increasing to 0.6 in. or 0.7 in. at heavy overloads. In fact, as normally designed and installed, forcing the boilers beyond 200 per cent. of rating is impossible without by-passing the economizer. Induced draft must be employed if the economizer is to be used at high ratings, because the draft losses limit the maximum capacity of the boilers obtainable with natural draft. If the temperature of gases is reduced from 550 deg. to 350 deg., the loss of draft is approximately 25 per cent.

**323. The capacity rating of economizers** is based on circulating 6.25 gal. of feed water per hr. per tube, and upon a heat transmission coefficient of 2.7 to 3 B.t.u.

**324. Economizer Dimensions and Capacities**

| No. of tubes | No. tubes wide | No. sections | Length of economizer | Clear height req'd | Height over sections | Width between walls | Capacity (lb. water) | Heating surface external (sq. ft.) |
|---|---|---|---|---|---|---|---|---|
| | | | Ft. In. | Ft. In. | Ft. In. | Ft. In. | | |
| 96 | 6 | 16 | 9 8 | 23 6 | 10 2½ | 4 8 | 6,000 | 960 |
| 144 | 6 | 24 | 14 6 | 23 6 | 10 2½ | 4 8 | 9,000 | 1,440 |
| 192 | 6 | 32 | 19 4 | 23 6 | 10 2½ | 4 8 | 12,000 | 1,920 |
| 240 | 6 | 40 | 24 2 | 23 6 | 10 2½ | 4 8 | 15,000 | 2,400 |
| 128 | 8 | 16 | 9 8 | 23 6 | 10 2½ | 6 0 | 8,000 | 1,280 |
| 256 | 8 | 32 | 19 4 | 23 6 | 10 2½ | 6 0 | 16,000 | 2,560 |
| 384 | 8 | 48 | 29 0 | 23 6 | 10 2½ | 6 0 | 24,000 | 3,840 |
| 512 | 8 | 64 | 38 8 | 23 6 | 10 2½ | 6 0 | 32,000 | 5,120 |
| 576 | 8 | 72 | 43 6 | 23 6 | 10 2½ | 6 0 | 36,000 | 5,760 |
| 160 | 10 | 16 | 9 8 | 23 6 | 10 2½ | 7 4 | 10,000 | 1,600 |
| 320 | 10 | 32 | 19 4 | 23 6 | 10 2½ | 7 4 | 20,000 | 3,200 |
| 480 | 10 | 48 | 29 0 | 23 6 | 10 2½ | 7 4 | 30,000 | 4,800 |
| 640 | 10 | 64 | 38 8 | 23 6 | 10 2½ | 7 4 | 40,000 | 6,400 |
| 800 | 10 | 80 | 48 4 | 23 6 | 10 2½ | 7 4 | 50,000 | 8,000 |

Any other number of sections in multiples of 4, from 8 to 80, can be employed, giving proportionate dimensions.

**325. Accumulation of soot** occurs upon the tubes, and the "sweating" which takes place at low feed temperatures tends to catch and hold the soot firmly. **Continuous scraping** of the tubes is employed to overcome this difficulty. The cast-iron scrapers are driven slowly up and down the tubes in pairs, requiring about 1 h.p. to every 300 or 350 boiler h.p. connected to the economizer. There is a friction rig on each scraper drive so that if any solid obstruction stops one scraper, it will neither break the scraper nor interfere with the others.

**326. The operation of economizers** requires attendance for the scrapers, cleaning the inside of the tubes, and cleaning soot and fine cinder from the

Digitized by Google

bottom of the economizer chamber. The first item is small, as the drive is usually by motor and the mechanism is very slow moving; the second depends on the feed water and should occur with less frequency than in the boilers; the last depends on the rate of driving and the coal, varying from once a month to once in four months.

**327. The cost of economizers** averages about $15.00 per tube, installed. The tubes are usually 4½ in. by 10 ft.; cast iron is employed throughout, since at the low rate of heat interchange, any other material would be too expensive. From the point of view of increased economy and the cost of securing it, the economizer is the least desirable of all auxiliaries. In many cases it cannot be made to pay; this is generally true if it saves less than 5 per cent. If it saves over 10 per cent., there is reason to conclude that the rest of the plant is being very badly operated.

## PUMPS

**328. The work done by a pump** is given by

$$W = wh \tag{53}$$

where $W$ = ft.-lb. of work per min. performed in lifting the water, $w$ = lb. of water pumped per min. and $h$ = sum of suction lift, discharge head and velocity head gained in the pump inlet and outlet, in ft. The water h.p. is equal to $wh$ divided by 33,000. The water pressure, or suction, in lb. per sq. in. divided by 0.434 equals the head in ft. at the discharge, or the suction, respectively, for water at 62 deg. fahr. The velocity head is

$$h_v = \frac{v}{\sqrt{2g}} \tag{54}$$

where $v$ = velocity of water in ft. per sec. and $\sqrt{2g} = 8.08$. For most cases, the velocity head in suction and discharge pipes may be disregarded, as it is not over 8 ft. per sec.

**329. The duty** is expressed

$$\text{Duty} = \left(\frac{\text{ft.-lb. of work done on water}}{\text{weight of dry steam}}\right)1{,}000 \tag{55}$$

or

$$\text{Duty} = \left(\frac{\text{ft.-lb. of work done on water}}{\text{Total B.t.u. used}}\right)1{,}000{,}000 \tag{56}$$

The latter definition of duty is more satisfactory than the first; duty always includes the efficiency of the steam end, as well as the water end.

**330. Pumps are broadly classed in four types**—reciprocating, centrifugal and turbine, rotary, and jet pumps. The **reciprocating type** can be subdivided into direct-acting, flywheel and power pumps. **The direct-acting type** has steam and water cylinders on a common piston rod, and no flywheel; the valve mechanism for the steam cylinder is actuated direct from the rod by tappets. This type may be single-cylinder, or duplex, and the steam cylinders may be simple, compound or triple expansion. **The duplex simple pump** is the most rugged and reliable of all. Outside-packed plungers are the most desirable, as the packing on the plunger is adjustable while running and the amount of leakage can be seen. **Flywheel pumps** are similar to the direct-acting type, except that a flywheel is added and the steam valve is gear driven from the shaft as in a steam engine. Pumping engines are a development of this type. **Power pumps** are fitted with one or more cylinders, driven from a crank shaft and belted or geared to the source of power. When three cylinders with cranks at 120 deg. are used, the pump is known as a triplex; this type is very frequently gear-driven from a motor or an internal combustion engine.

**331. Centrifugal pumps** are those in which pressure and flow is produced by a rotating impeller, which gives the water entering it an increase in velocity; this velocity is converted into pressure by a suitable whirlpool chamber or diffuser. **The obtainable head** is proportional to the square of the peripheral velocity of the impeller; this velocity is subject to practical limitations, so that 150 to 200 ft. head is about the upper limit desirable in a single impeller. For higher heads, such as boiler feeding, the pumps are made two, three or more stages, consisting merely of single impellers connected in series in a single casing.

Digitized by Google

**332. Rotary pumps** are very little used in power-station service; the commonest types are the bi-lobular type, and the gear pump. Neither has very good efficiency.

**333. Screw or propeller pumps,** while not strictly centrifugal, create pressure in the same manner, and are usually considered in the same class.

**334. Jet pumps** are covered in Par. 345 to 353.

**335. The characteristic curve of a centrifugal pump** is necessary for determining its behav or. The capacity of a reciprocating or a rotary pump varies directly with the speed and is substantially independent of the pressure. The usual graphs are between capacity and efficiency, and capacity and head. Fig. 40 gives results for a 6-in. single-stage pump. Pumps for similar service, but different sizes, will have about the same characteristics, the efficiency increasing slightly with the size.

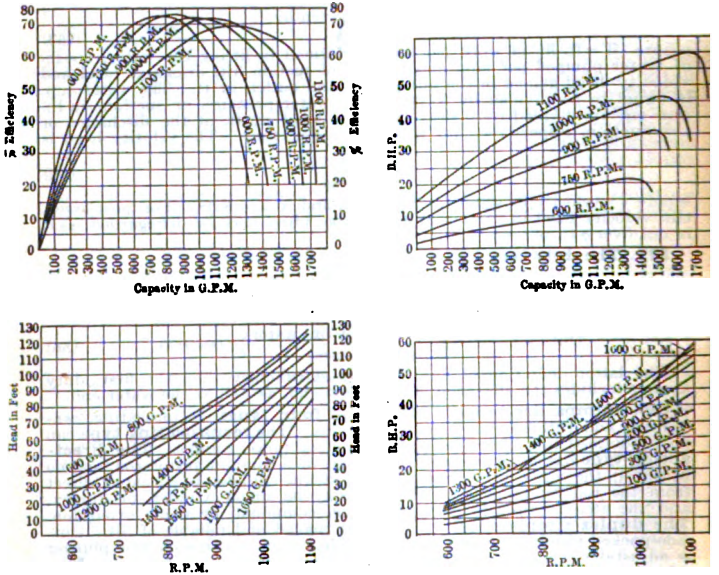

FIG. 40.—Characteristics of a 6-in. single-stage centrifugal pump.

**336. Boiler feed pumps** are usually the duplex outside-packed plunger type, or the three-stage or four-stage centrifugal. Occasional installations of motor-driven triplex pumps are made, but are undesirable. The principal feature required is reliability, which at once gives the steam-driven apparatus the precedence. The duplex direct-acting type was, until recently, almost exclusively used, but is now being replaced by the turbine-driven centrifugal. Fig. 40 shows that the pump speed is increased slightly as the delivery increases; this gives a more nearly constant head and a better efficiency with the variable loads.

**337. Pressure regulators** are employed to control the speed of all direct-acting boiler feed pumps and also, in most cases, for the centrifugal types.

**338. The efficiency of direct-acting steam simplex and duplex pumps** is low mechanically and thermally. The mechanical efficiency

Digitized by Google

(water h.p./indicated h.p.) varies from 0.50 in small pumps to 0.85. The water rates are very high, both on account of the low speed and the lack of expansion.

**339. Performance test of boiler feed pump.** The following test of economy of Marsh pumps was made at Armour Institute of Technology; size 12×7½×12 in.; steam actuated valve gear; initial pressure 100 lb. gage; back pressure 2 lb. gage.

| Number of strokes | Pump h.p. | Steam per indicated h.p.-hour | Number strokes | Pump h.p. | Steam per indicated h.p.-hour |
|---|---|---|---|---|---|
| 10 | 1.0 | 400 | 60 | 6.4 | 105 |
| 20 | 2.0 | 210 | 70 | 7.6 | 101 |
| 30 | 3.0 | 168 | 80 | 8.8 | 100 |
| 40 | 4.1 | 130 | 90 | 10.0 | 99 |
| 50 | 5.2 | 118 | 100 | 11.3 | 99 |

(G. F. GEBHARDT)

**340. The mechanical efficiency of geared triplex pumps** is high, running up to 0.82 for motor-driven and high-speed pumps; the low-speed geared pumps reach 0.70.

**341. The efficiency of centrifugal pumps** depends on the size and number of stages. De Laval gives the following data for volute pumps.

| Capacity | Efficiency | Capacity | Efficiency |
|---|---|---|---|
| 75– 250 g.p.m. | 55 to 65 | 3,000– 6,000 | 73 to 75 |
| 250– 900 | 70 | 6,000–10,000 | 75 to 78 |
| 900–3,000 | 70 to 73 | 10,000–up | 75 to 85 |

The maximum efficiency of two-stage pumps is about 70 to 75 per cent. of three-stage and four-stage pumps, about 60 to 68 per cent. These values apply to turbine speeds, as in turbine drive. The efficiency of a volute pump is usually stated at the proper speed for the head. At turbine speeds and under low head, the efficiency drops about 20 to 25 per cent; this is the case for turbine-driven circulating pumps, in which the speed is too high for efficient low-head pumping and still too low for efficient turbine water rates. The latest solution is a reversion to the de Laval geared drive, using helical gears.

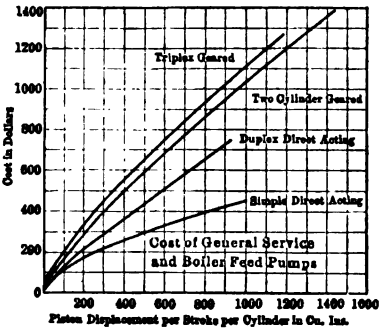

FIG. 41.—Costs of reciprocating pumps.

**342. Costs** are given in Fig. 41 for simplex and duplex pumps, and for triplex and two-cylinder geared power pumps. All costs are given in terms of displacement. The cost of large geared double-acting pumps is from $2.00 to $3.00 per cu. in. of displacement. The cost of single-stage centrifugal pumps is from $0.50 to $0.75 per gal. per min. of capacity. Multi-stage centrifugal pumps cost from $2.50 to $4.00 per gal. per min. of capacity.

**343. The usual piston speeds** at which capacity is calculated for piston pumps, are from 100 to 200 ft. per min. for strokes below 12 in. and 100 ft. per min. for all strokes longer than 12 in.

Digitized by Google

**344. Operation.** The direct-acting simplex or duplex steam pump requires almost no attention except occasional packing of glands and lubricating. When controlled by a pressure governor, the delivery is suited to the demand. It will run on water as well as steam, and little care need be taken to supply it with dry steam. The geared triplex type requires more careful attention on account of the additional parts to be lubricated; if motor-driven, it must be provided with a suitable speed control, or it cannot be used on variable load. Piston and rotary pumps must always be provided with relief valves in the discharge, as they are positive in action and will produce excessive pressures if the discharge is restricted.

Centrifugal pumps cannot discharge under a higher head than that corresponding to the speed, therefore no relief is needed; the reason for using pressure governors with turbine-driven centrifugal boiler feed pumps is to reduce the speed in proportion to the delivery in order to keep up the efficiency. Centrifugal pumps are generally ring oiled and therefore require very little attention. The packing of the glands where the shaft leaves the pump casing is usually water-sealed; for this purpose a clean cool water should be provided. All centrifugal pumps must be primed before they will operate, and if no vacuum apparatus is provided, a foot-valve on the suction pipe must be used to prevent the water draining out of the pump on shutting down. A discharge valve must be provided, to be closed when priming, until the pump develops pressure.

## JET PUMPS

**345. Jet pumps** operate by means of the kinetic energy of a rapidly moving stream of fluid. In those operated by steam, a jet of the high-pressure steam issues into a chamber at approximately atmospheric pressure or a little below, and there strikes the supply of water to be pumped. The impact of the steam transfers momentum to the water, which, together with the condensed steam, is hurled into a second nozzle which converts the kinetic energy of the mass into pressure and the stream enters the pressure chamber through a check valve. Since the water pumped must condense the steam used, it has a limitation in temperature, or the injector will fail to work.

**346. Injectors** are used for boiler feeding. For low and moderate pressures a single steam tube is used, both for lifting the water and forcing it into the boiler. But for heavier pressures and greater flexibility in handling variable quantities of water, and with wider range of pressure, the double-tube injector is employed. The first jet lifts the water to the second, or forcing jet.

**347. Capacity of Schütte & Koerting double-tube boiler-feed injectors,** in gal. per minute.

| Size No. | Size pipe (in.) | Steam pressure | | | Size No. | Size pipe (in.) | Steam pressure | | |
|---|---|---|---|---|---|---|---|---|---|
| | | 50 lb. | 100 lb. | 150 lb. | | | 50 lb. | 100 lb. | 150 lb. |
| 00 | ¼ | 33 | 48 | 60 | 6 | 1¼ | 825 | 990 | 1,125 |
| 0 | ¼ | 83 | 101 | 112 | 7 | 1½ | 1,072 | 1,372 | 1,612 |
| 1 | ¾ | 112 | 143 | 180 | 8 | 1½ | 1,388 | 1,800 | 2,115 |
| 2 | ½ | 172 | 210 | 232 | 9 | 2 | 1,688 | 2,100 | 2,475 |
| 3¼ | ¾ | 278 | 338 | 397 | 10 | 2 | 2,025 | 2,438 | 2,850 |
| 3½ | ¾ | 398 | 472 | 547 | 11 | 2–2½ | 2,530 | 3,050 | 3,515 |
| 4 | 1 | 533 | 622 | 720 | 12 | 2½ | 3,000 | 3,638 | 4,252 |
| 5 | 1¼ | 675 | 802 | 922 | | | | | |

The weight ranges from 3 to 108 lb.; No. 2 weighs 10 lb. and No. 4 weighs 20 lb.

**348. Ejectors** are either single-tube jet pumps, or direct-pressure pumps in which steam, or air, is admitted directly into a chamber filled by gravity with the liquid to be pumped. The pressure closes the inlet check valve and forces the water or other liquid out; when the chamber is emptied, a float therein drops and relieves the pressure, allowing the chamber to fill again. As the liquid reaches the top, the float rises and readmits pressure. The Shone and Albany traps are examples.

Digitized by Google

**348. Inspirators** are injectors of the double-tube type (Par. 346).

**350. Siphons**, so called, are single-tube jet pumps used for lifting only. Air, steam, or high-pressure water may be the motive force. They are not used for forcing against more than a few feet head.

**351. Pulsometers** comprise another form of direct-pressure pump like the ejector, and operate in much the same manner. The operating steam is condensed by the cold-water chamber and, in collapsing to water, draws the chamber full of water and operates a ball valve to admit steam again. There are always two chambers, one filling and one discharging, operated by the single ball valve. The pulsometer, therefore, can lift water by suction, whereas the pressure-type ejector must be primed by gravity.

**352. Efficiency.** If the mechanical efficiency alone is considered, all jet pumps are very inefficient, being more wasteful of steam than the direct-acting steam pump. But thermally considered, the steam injector is nearly 100 per cent. efficient, since the heat of the exhaust steam is returned in the feed water. The siphon and the pulsometer are convenient for temporary use and for drainage of pits under conditions adverse to the use of machinery.

**353. The cost of these classes** varies so widely that representative figures can hardly be given, $2 to $5 per 100 g.p.m. capacity covers most cases.

## PIPING

**354. The requirements of piping** are: (a) tightness against leakage; (b) reasonably small pressure loss through friction; (c) suitable provision for change of length through change of temperature of the fluid contained; (d) reasonably small loss of heat by radiation if the fluid is hot, and intended to be kept so. Most of these requirements increase the first cost; a balance must therefore be found beyond which it does not pay to carry refinements.

**355. The flow of steam** is expressed by Babcock as

$$W = 87\left\{\frac{\gamma P d^5}{L\left(1+\frac{3.6}{d}\right)}\right\}^{\frac{1}{2}} \tag{57}$$

$$P = 0.0001321\left(\frac{W^2 L\left(1+\frac{3.6}{d}\right)}{\gamma d^5}\right) \tag{58}$$

where $W$ = lb. steam flowing per min., $L$ = pipe length in ft., $d$ = inside diameter of pipe in in., $\gamma$ = mean density of steam at pressures in the pipe and $P$ = pressure drop in. lb. per sq. in.

**356. Steam-flow for 1-lb. drop computed by Babcock's formula**

| Initial pressure lb. gage | Weight of steam per min. in pounds with 1 lb. drop of pressure, in length of 240 pipe diameters | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | Nominal pipe diameter (in.) | | | | | | | | | | |
| | ¾ | 1 | 1¼ | 2 | 2½ | 3 | 4 | 6 | 8 | 10 | 12 |
| 1 | 1.16 | 2.07 | 5.7 | 10.27 | 15.45 | 25.38 | 46.85 | 115.9 | 211.4 | 341.1 | 502.4 |
| 10 | 1.44 | 2.57 | 7.1 | 12.72 | 19.15 | 31.45 | 58.05 | 143.6 | 262.0 | 422.7 | 622.5 |
| 50 | 2.27 | 4.04 | 11.2 | 20.01 | 30.13 | 49.48 | 91.34 | 226.0 | 412.2 | 665.0 | 979.5 |
| 80 | 2.71 | 4.82 | 13.3 | 23.82 | 35.87 | 58.91 | 108.74 | 269.0 | 490.7 | 791.7 | 1166.1 |
| 100 | 2.95 | 5.25 | 14.5 | 25.96 | 39.07 | 64.18 | 118.47 | 293.1 | 534.6 | 862.6 | 1270.1 |
| 150 | 3.45 | 6.14 | 17.0 | 30.37 | 45.72 | 75.09 | 138.61 | 343.0 | 625.5 | 1009.2 | 1486.5 |

**357. The flow of water in long pipes** is given by Church as

$$Q = 3.15\sqrt{\frac{d^5 h}{fl}} \tag{59}$$

where $Q$ = cu ft. per sec., $d$ = diameter pipe in ft., $h$ = head of water in ft., $f$ = coefficient of friction and $l$ = length of pipe in ft.

Digitized by Google

For pipe under 500 diameters in length,

$$Q = 6.3\sqrt{\frac{d^5 h}{(1+0.5)d+4fl}} \qquad (60)$$

**358. The loss of head due to friction** is given by Weisbach as

$$H = \left(0.0144 + \frac{0.01716}{\sqrt{V}}\right)\frac{V^2}{5.367d^1} \qquad (61)$$

where $H$ = friction head in ft., $V$ = velocity of water in ft. per sec. and $d^1$ = diameter of pipe in in.

**359. Equivalent length of valves and elbows.** The above formulas for steam and water (Par. **357** and **358**) apply to straight pipes. Valves and elbows may be figured as equivalent to lengths of straight pipe as follows, **for steam,**

$$L = \frac{6.33\,d}{\left(1+\frac{3.6}{d}\right)} \text{ for each 90 deg. ell} \qquad (62)$$

$$L = \frac{9.5d}{\left(1+\frac{3.6}{d}\right)} \text{ for each globe and angle valve,} \qquad (63)$$

where $L$ = equivalent length of straight pipe in ft., and $d$ = diam. of pipe in in. Gate valves are not considered. **For water,**

$$H = C\left(\frac{V^2}{2g}\right) \qquad (64)$$

where $C$ = coefficient, 0.182 for 45 deg. ells, 0.98 for 90 deg. ells, 0.182 for **gate** valves, 1.91 for globe valves, and 2.94 for angle globe valves.

**360. The principal piping systems** are: high-pressure steam; exhaust or low-pressure steam; hot, cold and circulating water piping; and oil piping.

**361. High-pressure steam piping** is made chiefly of steel pipe with cast-iron fittings, if saturated steam is used; if superheat is employed, cast-steel fittings and valves must be used, as cast-iron will not stand the temperature. For any pressure up to 125 lb. per sq. in. **standard fittings** are used; above 125 lb. **extra heavy fittings. Screwed** fittings should not be used above 3-in. pipe sizes; all larger material should be **flanged.**

**362. On exhaust lines,** standard weight pipe and fittings are usually employed; for very large sizes, however, special light-weight fittings may be used to save weight and first cost. Screwed pipe may be used up to 8-in. pipe sizes, but flanged fittings are preferable for everything over 4 in. Spiral riveted galvanized pipe may be used in place of standard pipe, as it is very much lighter and perfectly suitable for moderate pressures. It cannot be used on vacuum work.

**363. Hot and cold water mains** are made up the same as live steam lines; except that in some cases cast-iron pipe as well as fittings are employed throughout on high-pressure hot-water service, to minimise corrosion effects. No cast-steel fittings are necessary. For circulating water lines, galvanized spiral riveted pipe is useful for fresh water, but cast-iron pipe is generally used throughout for salt water and is preferable even for fresh water.

**364. Oil systems** were generally installed in brass pipe and fittings on the supply to engines; but it has been found that steel pipe, if well cleaned, is perfectly satisfactory for the service. There is little excuse for the use of brass piping except for appearance, on gage fittings, or for some special service where corrosion would be fatal.

**365. There are four principal systems of piping arrangements:** individual supply; ring; header; and unit (Fig. 42). The **individual supply** is really not a system, but the lack of it, and should not be employed.

**366. The ring system** is a development of the duplicate header; all supply lines tap in on one side of the ring, all demand lines on the other; by means of sectionalising valves in the main, any section may be isolated without interfering with the rest of the plant.

Digitized by Google

**367. In the header system,** all supply and demand lines tap to one large main; so that if any section is cut out, it must interfere to some extent with the operation of the plant. This feature may not be serious; but for large power stations it is undesirable.

**368. Unit system.** The modern tendency is to revert to the unit system. This is the individual supply system—each group of boilers supplying its own turbine, but the units are tied together by equalizer pipes; so that there is really a header of diminished capacity between the units. Fig. 42 gives typical examples.

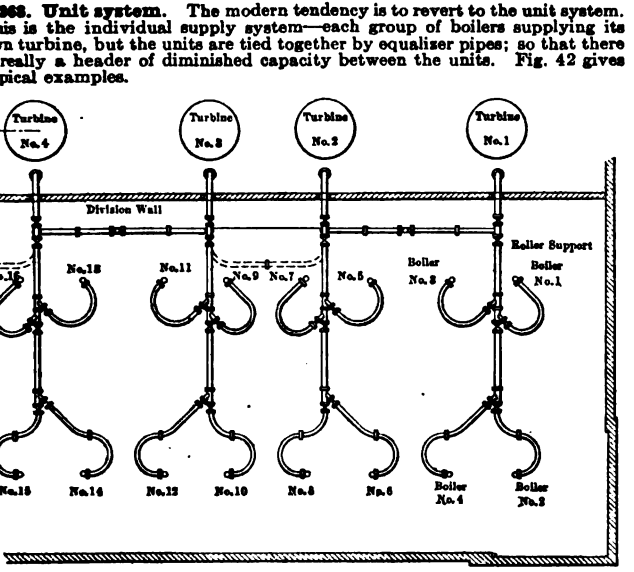

FIG. 42.—Piping systems.

**369. Expansion** in steel and cast-iron pipe may be taken as 0.9 in. per 100 deg. temperature difference from atmosphere, per 100 ft. of pipe under average conditions. **Expansion joints** should be provided every 50 ft. of straight steam main; every 75 or 100 ft. will do for water or exhaust steam. See Sec. 4, for coefficients of expansion of piping materials.

**370. The slip expansion joint** is useful for water service and exhaust steam at atmospheric pressure. It should never be used for high-pressure steam or vacuum; its capacity can be anything up to 9 in. or 10 in. of movement.

**371. The copper bellows joint** is very successful for low-pressure steam and vacuum work, particularly the type having only one corrugation. Its capacity however is never over 0.5 to 1 in. of expansion, and preferably not over 0.25 in. This type of joint is sometimes made up of boiler plate for high-pressure steam service.

**372. The pipe bend** is the simplest and safest joint for high-pressure steam and is usually made of as large radius as can conveniently be made, taking care of from 1.5 to 2 in. of expansion per bend.

**373. Avoidance of strains in fittings.** Piping should always be laid out so that expansion will not bring strains upon cast-iron fittings, but upon the expansion joints, or at least upon the more flexible steel pipe.

**374. Condensation in steam pipes** is due to radiation; it occurs only in saturated steam mains. All low points in the piping system and all dead ends or pockets where water can collect, must be drained. The usual method for

Digitized by Google

high-pressure steam is to connect a steam trap at each point to be drained and can be returned direct to the boilers, or to the feed tanks. Low-pressure steam mains are usually drained by gravity through an inverted siphon leg, to act as a steam seal.

**375. Steam traps** are of four principal types: bucket, float, tilting and expansion. The bucket and tilting traps are probably the most reliable.

**376. Separators** are employed to remove moisture from the steam before it is supplied to an engine. In every instance short and sudden turns are employed to throw out the moisture by centrifugal force, and a large chamber is then provided to reduce the velocity of the steam and act as a reservoir to collect and retain the water. (See Fig. 20a.)

**377. Controlling valves** are of three types: gate, globe and angle. The **globe valve** is always used for stop or throttle work. The **angle valve** is really a globe valve with the outlet turned through 90 deg. and is used as a globe valve, usually for the stop valve on boilers. For all other steam work the **gate valve** should be used on account of offering practically no obstruction to steam flow. All exhaust valves should be of the gate type. For water service, gate valves should be used wherever possible. **Check valves** may be horizontal, vertical, and swing. The horizontal and vertical check valves ordinarily are built much like a globe valve, but the valve disc has no stem and wheel for closing it.

**378. Relief and back-pressure valves** are developed from the check valve, with a spring or lever and weight loading device, so that a definite pressure under the valve disc will lift the valve and let off pressure. Relief valves are used on the discharge of reciprocating pumps to prevent excessive pressures; also on cylinders and receivers of steam engines. Back pressure and atmospheric relief valves are used on exhaust steam systems and condensers respectively. All of these types are emergency valves, to pre ent damage under unusual conditions.

**379. Reducing valves** are usually double-seated, or balanced, valves, with a pressure diaphragm substituted for the spring of the relief valves. This diaphragm is connected to the discharge side of the valve, and operates to close the valve only when the pressure on the discharge side rises above the predetermined amount. They are used to feed high-pressure steam into low-pressure systems.

**380. The three principal types of pipe joint** used are; screwed, flanged, and bell and spigot. The **screwed joint** is used for all pressures and service up to 3-in. diameter of pipe, and up to 12 in. for low-pressure service. Above 3 in. in high-pressure service and 12-in low-pressure service the **flanged joint** in one of its forms is used.

**381. The principal methods of attaching flanges** to steel pipe are: screwed flanges, peened flanges and, lately, machine expanded flanges, welded flanges and lap flanges. Of these, **screwed flanges** are in common use for low-pressure work, and high-pressure work up to 100 lb. in any size, or up to 200 lb. in sizes not larger than 6-in. or 8-in. diameter. It is a cheap and satisfactory joint when well made.

**382. A much better joint for high pressures is the lap joint,** in which the pipe is lapped over onto the flange and then faced off. The **welded joint** is also satisfactory but more expensive. The new **machine-expanded joint,** in which the pipe is rolled into a recess in the flange, promises well and is cheap to make.

**383. Gaskets** for low-pressure work may be of rubber compounds or asbestos. For high-pressure steam, asbestos, and the metallic gaskets, such as corrugated copper, are better.

**384. Bursting pressure of standard mild steel pipe.** Tests made at the Armour Institute of Technology on 5-ft. random specimens capped at both ends gave average results as follows: 1-in., 7,730 lb. per sq. in.; 2-in., 5,080 lb.; 4-in., 1,750 lb.; 5-in., 2,550 lb.; 6-in., 3,200 lb.; 10-in., 1,800 lb.; 12-in., 2.500 lb. On the 4-in., 5-in., 6-in., 10-in. and 12-in. sizes failure occurred at the threaded end.

**385. Pipe covering** is practically always justified for high-pressure steam, and for exhaust also, if used for heating feed water. Hot feed-water pipes

Digitized by Google

should also be covered. The standard coverings are principally magnesia, asbestos and the fossil meal compounds. Moulded sectional covering can be obtained for pipes up to 12-in. diameter in single (1-in.) and double (2-in. to 3-in.) thickness. All exhaust lines should be covered with single thickness; all steam lines, with double thickness. Usually the covering is bought already canvassed. For larger size pipe than 12 in., sectional blocks, about 1.5 in. × 3 in. × 18 in. are used, and wired on; then the joints are pasted with asbestos cement and the whole is canvassed and painted. Moulded covering can be bought in shapes to fit standard fittings, such as tees and ells, but is frequently made up from blocking and asbestos cement.

**386. The radiation losses** from uncovered pipe are given by

$$Q = A(T_1 - T_2)U \tag{65}$$

where $A$ = sq. ft. of radiating surface, $T_1$ = temperature of steam within the pipe, $T_2$ = temperature of air outside, and $U$ = transmission coefficient = 2.7 B.t.u. per sq. ft. per hr. per degree of temperature difference.

For 1-in. magnesia, 85 per cent., $U = 0.4 - 0.5$ (66)

For 1.5-in. magnesia, 85 per cent., $U = 0.25 - 0.3$ (67)

In a modern plant, with properly covered piping the actual radiation loss from pipe alone should not exceed 1 per cent. of the total heat of steam passing through at full load.

**387. Tests of Relative Efficiencies of Steam-pipe Coverings**

| Kind of covering | Size of pipe, inches | Thickness of covering, in. | B.t.u. per sq. ft. per deg. diff. of temp. | Per cent. heat lost | Authority |
|---|---|---|---|---|---|
| Bare pipe | ..... | ..... | 2.7 | 100 | ..... |
| Hair felt | 2 | 0.96 | 0.387 | 14.3 | Jacobus |
| Reman t | 2 | 0.88 | 0.434 | 16.1 | Jacobus |
| Solid cork | 2 | 1.20 | 0.427 | 15.8 | Stott |
| Magnesia | 2 | 1.16 | 0.439 | 16.3 | Stott |
| Magnesia | 4 | 1.12 | 0.465 | 17.2 | Norton |
| Asbestos sponge felted | 10 | 1.63 | 0.280 | 10.4 | Barrus |
| Asbestos sponge felted | 2 | 1.21 | 0.490 | 18.1 | Barrus |
| Manville sectional | 4 | 1.25 | 0.453 | 16.8 | Norton |
| Manville sectional | 2 | 1.31 | 0.572 | 21.2 | Paulding |

| Asbestos fire felt | 2 | 1.00 | 0.721 | 26.7 | Paulding |

(Abstracted from "Book of Standards," National Tube Co., Pittsburgh, Pa.)

**388. Exhaust heads** comprise a form of separator in which the entrained moisture in atmospheric exhaust is removed so that the issuing steam may not be a nuisance to the neighborhood, or an injury to the roof. They operate on the same centrifugal principle as separators.

**389. Blow-off valves and piping**, being subject to rapid variation from low to high temperature, must be carefully designed for expansion. As solid scale and rust flakes must be passed, the turns should be easy, and all connections between individual boilers and mains should be by 45-deg. laterals instead of tees.

**390. The installation of piping** should be done with great care to provide good alignment. Pipe joints can be made when piping is considerably out of line, as the lines are more or less flexible, but satisfactory joints and service cannot be expected. For **high-pressure** work, it is unsafe to strain the pipe in order to joint it. It is therefore good practice to arrange connections for flexibility, in case of variation from drawing dimensions; or better, to leave certain pieces of pipe called **fillers**, to be cut to field dimensions. This entails a slight delay in erection but is safe and eminently satisfactory.

Digitized by Google

All steam piping, and most water and oil piping, should be carefully **cleaned of internal scale** (by brushing or hammering), as this may dislodge during operation and cause trouble in the cylinders of engines or other apparatus. Steam and water piping should be tested at the working pressure before being put in service.

**391. Hangers.** Careful provision for hangers at suitable points must be made in order to support the pipe properly. The interval between hangers should not exceed 12 ft. except for small pipe, which may be supported on centers as much as 18 ft. apart.

**392. Costs.** Valves cost, in cast-iron body, approximately \$0.20 to \$0.25 per lb; straight cast-iron pipe, 12-ft. lengths, \$34.00 to \$50.00 per ton; straight pipe, shorter than 12-ft. lengths, \$52.00 to \$60.00 per ton; standard fittings, \$60.00 to \$75.00; special fittings, \$73.00 to \$113.00 per ton. Wrought-iron and steel pipe, 1-in. to 6-in. sizes, costs from 3.4 to 4.5 cents per lb.; 7-in. and 8-in. 4.3 to 5 cents; 10-in. to 12-in., 5 to 6 cents per lb. All the recent evidence seems to show that wrought-iron pipe is no better than steel for practically all purposes; and as the steel pipe is lower in price and more readily available, it is satisfactory to use it.

## PLANT ENSEMBLE

**393. The best combination of plant equipment** is seldom if ever one in which each piece of apparatus is chosen by reason of its best water rate, or highest efficiency. The characteristic under variable load and the heat relation to the rest of the plant are most important.

**394. The question of first cost versus economy** is discussed under power-plant economics (Par. **382** to **385**). The following paragraphs cover the best capacity and grouping of units for the best overall economy, with given efficiencies in the individual apparatus.

**395. The heat analysis in B.t.u.** is valuable for the purpose of proving the expected economies of any given combination of apparatus. Starting with the coal supplied, the boiler-room distribution of all the heat contents is followed through, including the B.t.u. delivered to steam, flues, unburned combustible, radiation, leakage, stoker, fan, and boiler feed-pump drives, other auxiliaries and miscellaneous steam such as boiler blow-down, free drip, dusting tubes, etc. In the engine room, the B.t.u. supplied in the steam is separated into pipe and engine radiation, exhaust drips, condenser auxiliaries, oil pumps, exciters, friction, electrical losses and energy delivered to bus bars. Heat returned by feed-water heaters and economizers is credited.

**396. The average conditions in a large metropolitan station** were given in a paper by H. G. Stott, on "Power Plant Economics" (A. I. E. E. Transactions, 1906), Par. **915**. Recomputed several years later, under improved conditions, the same plant showed, using coal having 14,000 B.t.u. per lb. net:

| | Per cent. | Per cent. | | Per cent. | Per cent. |
|---|---|---|---|---|---|
| Coal | | 100.0 | Circ. water pumps | 4.0 | |
| Ash loss* | 3.0 | | Boiler feed pumps | 1.0 | |
| Stack loss* | 19.0 | | Leakage and drips included in pipe radiation | | |
| Incomplete combustion | 5.1 | | Small auxiliaries | 1.3 | |
| Boiler radiation and leakage* | 8.0 | | Heating | 0.2 | |
| Returned by F. W. heaters | | 6.1 | Engine friction | 1.0 | |
| Returned by economizers | | 5.7 | Electrical losses | 0.3 | |
| Pipe radiation and leakage | 4.5 | | Engine radiation | 1.1 | |
| Tank radiation | 0.3 | | Rejected to condensers | 51.3 | |
| | | | House auxiliaries | 0.2 | |
| | | | To switchboard | 11.5 | |
| | | | Total | 111.8 | 111.8 |

* 65 per cent. boiler efficiency, including banking fires.

Digitized by Google

**397. In choosing the number and capacity of prime movers,** the **Willans line** of total steam consumption with load is plotted. The arrangement which gives the least area under the curve is the most economical. Fig. 43 shows this curve for 42-in. × 86-in. × 60-in. double compound Corliss engines, 7,500 kw. maximum continuous rating on 190 lb. dry steam, 28 in. vacuum. If the auxiliaries were not considered, the Willans line for engines alone would show the proper points for cutting engines in and out. It is found, however, that the most economical method is to carry up the load on $n$ units until the Willans line for $n$ units intersects the Willans line for $n+1$ units; and *vice versa*. The maximum capacity of individual machines may limit the cutting-in point somewhat when only one or two engines are running, but as the number in service increases, the loads on each engine before and after cutting in another unit become nearer alike.

**398. Effect of auxiliaries on Willans line.** The condensers and other auxiliaries using steam necessitate the addition of their demand to the main-unit demand, and the resulting Willans lines will give the steam demand of the engine room for any load. This supposes the units to be all alike and equally loaded when on the line; however, for units of unequal capacities, various loadings should be tried and plotted in order to determine the most economical operating conditions (Fig. 43).

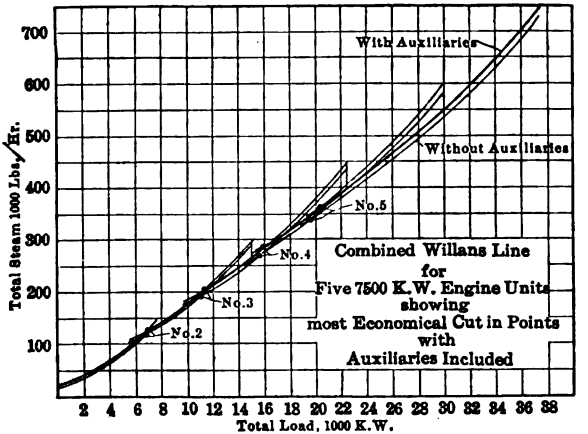

FIG. 43.—Willans line for 7500-kw. engines.

**399. The boiler generation curve** is determined by the efficiency of the boiler and stoker and by the steam required for forced draft, stoker drive, boiler feed pumps, etc. The economical cutting in and out points can be developed in the same manner as for the engine room, noting always that it is the overall efficiency which is important, not that of the boiler alone.

**400. Feed-water heaters** recover from 5 to 15 per cent. of the heat of the steam, the source being chiefly the exhaust from auxiliaries operated non-condensing. The feed-water heater always pays for itself.

**401. Economizers** recover from 3 to 10 per cent. of the total heat; but the re ent increase of boiler efficiency (reducing the stack temperatures), the reversion to all-steam auxiliaries, and the need for more draft at higher capacities, is rapidly limiting the field of the economizer; it does not always economise.

**402. Possible reductions in the heat losses.** The heat losses are given in Par. **396.** It is clear that: (a) the ash loss cannot be much reduced;

Digitized by Google

(b) the stack loss is probably susceptible of considerable improvement, especially by way of improving combustion, which affects stack temperature indirectly; (c) the incomplete combustion would be decreased with (b); (d) the condenser loss is the only other very considerable item, and this cannot, by nature of the cycle, be appreciably altered.

**403. The steam consumption per kw-hr.** of the plant will depend upon the water rate of the main unit, the steam required by auxiliaries and the load factor. The no-load steam losses include: banked boilers; pipe radiation and leakage; boiler blow-down; boiler dusting; operation of condenser auxiliaries on emergency units and boiler auxiliaries, and supplying feed water for these losses. If the load factor is low, these bear a larger proportion to the total. In a high-grade plant with a yearly load factor of 30 to 40 per cent., the station water rate is 25 to 35 per cent. higher than the best water rate of the main unit. For ordinary stations of moderate size on less than 25 to 40 per cent. load factor, the station water rate is 80 to 100 per cent. higher than that of the main unit alone. The steam required for condenser auxiliaries is from 2 to 3½ per cent. of the main-unit consumption, for engine units, up to 27 in. vacuum; for turbine plants, 4.5 to 10 per cent for 28 in. to 28.5 in. vacuum. The boiler feed-pump steam varies from 1 to 1½ per cent. for direct reciprocating pumps, and 0.6 to 1.3 per cent. for high-grade pumping engines, or turbine-driven centrifugal types. The steam for forced-draft fans on underfeed stokers varies from 1 to 2 per cent. of main-unit steam; coal-conveying systems require 1.7 to 3 per cent., or the equivalent in electrical energy. The total varies therefore from 8 to 18 per cent.

**404. The power taken by the auxiliaries of a 5,000-kw. turbine** tested by the Edison Illuminating Co. of Boston was as follows:

| | | | |
|---|---|---|---|
| Kw. on turbine | 2,713.0 | 3,410.0 | 4,758.0 |
| Vacuum, in. | 28.4 | 28.7 | 28.6 |
| Barometer, in. | 29.53 | 29.95 | 29.96 |
| I.h.p. of boiler-feed pump | 13.9 | 23.7 | 27.2 |
| I.h.p. of circulating pump | 69.1 | 69.1 | 69.1 |
| I.h.p. of dry-vacuum pump | 24.3 | 23.2 | 23.8 |
| I.h.p. of step-bearing pump | 6.4 | 5.8 | 5.6 |
| Total power for auxiliaries | 122.3 | 131.0 | 135.7 |
| Per cent. power of auxiliaries | 3.4 | 2.9 | 2.1 |
| Per cent. water used by auxiliaries | 8.4 | 7.4 | 5.7 |
| Electric h.p. of wet-vacuum pump | 8.6 | 9.2 | 9.8 |

**405. Number of main units.** In modern central-station practice, the reciprocating engine is practically defunct. For 24-hr. service, not less than three turbine units should be employed and preferably six to eight for large stations. The units should always be of similar size. The analysis given in Par. **397** to **399** will prove that there is very seldom any economy in selecting odd-size units for a plant, and there is always increased risk of shutdown and increased cost, due to lack of interchangeability of units and spare parts.

**406. Steam versus electric drive for auxiliaries.** The heat analysis shows that the steam auxiliary is always more economical than the motor-driven type, when the amount of steam required for auxiliaries does not exceed the demand for heat in the feed water. Turbine-driven auxiliaries are practically universal except for the dry-vacuum pumps, which are often reciprocating, and small oil pumps, which are more satisfactory if duplex direct acting. Turbine-driven blast fans are becoming very widely used. Turbine-driven centrifugal boiler feed pumps are very satisfactory in units larger than 300 gal. per min.; in smaller units, the impeller passages are small and likely to give trouble from scaling and clogging.

**407. General plant layout.** The most generally satisfactory scheme is to lay out the plant on the **unit system**, with a complete set of boilers and auxiliaries for each turbine. The advantages become more and more marked, the larger the plant.

**408. Plant location.** The plant should be located at the edge of a sufficient body of water to supply abundant condensing water; where this cannot be done, wells may possibly supply the required amount, or, failing this, cool-

Digitized by Google

ing towers will be necessary. The next most important consideration is coal supply; location on a river or at tide-water may automatically take care of coal supply by barge, but otherwise a rail connection will be needed. The third item is suitable ground for the foundations of the building and machinery. Choice of site where rock bottom is available near the surface is most desirable, but hardpan is practically as satisfactory. On marsh land near rivers or tide-water, piling or fill will be necessary. Too great pains to provide solid and permanent foundations cannot be taken.

**409. Load factor** plays a large part in selection of a plant; for low load factors, the fixed charges are high, and the operating charges relatively small. It is therefore necessary to cut down the first cost, which is done by omitting reinements for efficiency and allowing the thermal economy to go down. For high load factor, the fixed charges are less important and operating charges become the controlling factor; therefore profitable investment in devices for high thermal economy may be made. For low load factors, machines with high overload capacities are desirable, at the sacrifice of economy. It will be desirable to overstoker the boilers a little, to this end, as well as to build the turbines for high overloads.

**410. Reserve capacity** of one main unit at peak load should be maintained in plants of any number of units up to eight; above this, two reserve units. This applies to plants with duplicate equipment. For plants with dissimilar units, the reserve should be equal to the largest unit in the plant, either as one large unit, or the equivalent load capacity in smaller units.

**411. Unit costs of equipment** may be taken as given in Par. **57, 88,** etc. But on a basis of plant output, the relations will be different. Lyford and Stovel give the following central station costs, high and low, for steam turbo-electric generating stations of 2,000 to 20,000 kw. capacity, based on maximum continuous capacity of generators as 50 deg. Cent. temp. rise.

| | Dollars per kw. | |
|---|---|---|
| | High | Low |
| Preparing Site: Clearing structures from site, construction roads, tracks, etc. | $0.25 | ..... |
| Yard Work: Flumes for condensing water, siding, grading, fencing, sidewalks, etc. | 2.50 | $1.00 |
| Foundations: Foundations for building, stacks and machinery, excavation, piling, waterproofing, etc. | 6.00<br>6.00 | 1.00<br>1.00 |
| Building: Frame, walls, floors, roofs, windows, doors, coal bunker, etc., exclusive of foundations, heating, plumbing and lighting. | 12.00 | 4.00 |
| Boiler-room Equipments: Boilers, stokers, flues, stacks, feed pumps, feed-water heater, economizers, mechanical draft, piping and covering, except condenser water piping. | 24.00 | 12.00 |
| Turbine Room Equipment: Steam turbines and generators, condensers, condenser auxiliaries, condenser water piping, oiling system, etc. | 22.00 | 12.00 |
| Electrical Switching Equipment: Exciters, masonry switch structure, switchboards, switches, instruments, etc., all wiring except for lighting. | 5.00 | 2.00 |
| Service Equipment: Cranes, lighting, heating, plumbing, fire protection, compressed air, furniture, permanent tools, coal- and ash-handling machinery, etc. | 5.00 | 2.50 |
| Starting Up: Labor, fuel and supplies for getting plant ready to carry useful load. | 1.00 | 0.50 |
| General Charges: Engineering, purchasing, supervision, clerical work, construction plant and supplies, watchmen, cleaning up, etc. | 6.00 | 3.00 |
| Total cost of plant, except land and interest during Construction. | $83.75 | $38.00 |

Digitized by Google

**412. Reliability** is increased by uniform equipment, and by proper reserves. The turbine plant is superior to the engine plant in this respect, with the same number and capacity of units. It is not good practice to operate a unit regularly at overloads, although the machine may always be overloaded for short periods before cutting in or after cutting out a unit. The analysis given in Par. **397** to **399** will show this to be thermally economical.

**413. Labor requirements** vary with station arrangements: roughly, for reciprocating engines, one man is required per 750 to 1,000 kw. in the engine room, and one man per 1,000 to 1,500 kw. in turbine stations. This includes switchboard and electrical attendance for operation only. Maintenance and repairs will need about 10 to 15 per cent. additional labor.

For the boiler room, one man is required per 600 to 800 kw. with overfeed stokers and one man per 800 to 1,500 kw. with underfeed types. The total for engine plants will be from 300 to 450 kw. per man for engine plants and 400 to 725 kw. for turbine plants, for operation only; for maintenance add 10 to 15 per cent. to the number of men required for operation.

**414. Relative Costs per Kw-hr. Distribution of Maintenance and Operation** (H. G. Stott)

| | Reciprocating steam plant | Steam turbine plant | Reciprocating engines and low-pressure steam turbines | Gas-engine plant | Gas engines and steam turbines | Hydraulic |
|---|---|---|---|---|---|---|
| MAINTENANCE | | | | | | |
| 1. Engine room, mechanical. | 2.59 | 0.51 | 1.55 | 5.18 | 2.84 | 0.51 |
| 2. Boiler or producer room. | 4.65 | 4.33 | 3.55 | 1.16 | 1.97 | ..... |
| 3. Coal and ash-handling apparatus. | 0.58 | 0.54 | 0.44 | 0.29 | 0.29 | ..... |
| 4. Electrical apparatus. | 1.13 | 1.13 | 1.13 | 1.13 | 1.13 | 1.13 |
| OPERATION | | | | | | |
| 5. Coal..... | 61.70 | 55.53 | 52.44 | 26.52 | 25.97 | ..... |
| 6. Water..... | 7.20 | 0.65 | 0.61 | 3.60 | 2.16 | ..... |
| 7. Engine room, labor. | 6.75 | 1.36 | 4.06 | 6.76 | 4.06 | 1.36 |
| 8. Boiler or producer room labor. | 7.20 | 6.74 | 5.50 | 1.81 | 3.05 | ..... |
| 9. Coal and ash-handling labor. | 2.28 | 2.13 | 1.75 | 1.14 | 1.14 | ..... |
| 10. Ash removal..... | 1.07 | 0.95 | 0.81 | 0.54 | 0.54 | ..... |
| 11. Electrical labor... | 2.54 | 2.54 | 2.54 | 2.54 | 2.54 | 2.54 |
| 12. Engine-room lubrication. | 1.78 | 0.35 | 1.02 | 1.80 | 1.07 | 0.20 |
| 13. Engine-room waste, etc. | 0.30 | 0.30 | 0.30 | 0.30 | 0.30 | 0.20 |
| 14. Boiler-room lubrication, etc. | 0.17 | 0.17 | 0.17 | 0.17 | 0.17 | ..... |
| Relative operating cost per cent. | 100.00 | 77.23 | 75.87 | 52.94 | 47.23 | 5.94 |
| Relative investment per cent. | 100.00 | 75.00 | 80.00 | 110.00 | 96.20 | 100.00 |
| Probable average cost per kw. | 125.00 | 93.75 | 100.00 | 137.50 | 120.00 | 125.00 |
| Probable fixed charges per cent. | 11.00 | 11.00 | 11.00 | 12.00 | 11.50 | 11.00 |

For steam-turbine plants larger than 60,000 kw. the cost per kw. may be reduced to $75.

Digitized by Google

## TESTING

**415. Boiler-testing** requires the following essential data: (a) Weight of water fed per hr.; (b) weight of coal fed per hr.; (c) quality of steam; (d) pressure and superheat; (e) feed-water temperature; (f) proximate analysis of coal including moisture and B.t.u. per lb. Additional desirable data includes: (g) Flue temperature, including furnace and pass temperatures; (h) flue gas analysis, and analyses of gas at various points in boiler; (j) weight of refuse; (k) proximate analysis of refuse, moisture and B.t.u. per lb.; (l) siftings, if stoker fired; (m) soot and dust passing through boiler; (n) steam flow by meters. Boiler testing is always interwoven with stoker testing; the fire and the heating surface are tested together. **The duration of test** should never be less than 24 hr., for the most accurate results.

**416. For weighing feed water**, tanks on platform scales are best: but lacking these, a calibrated recording Venturi meter is satisfactory and accurate within 1 per cent. on reasonably steady flow.

**417. For full details as to methods of firing, calorimetry, etc.**, see standard rules of the A. S. M. E.

**418. Heat Balance, or Distribution of the Heating Value of the Combustible**

| The heat value of 1 lb. of combustible | B.t.u. | |
|---|---|---|
| | B.t.u. | Per cent. |
| 1. Heat absorbed by the boiler = evaporation from and at 212° per lb. of combustible × 965.7. | | |
| 2. Loss due to moisture in coal = per cent. of moisture referred to combustible ÷ 100 × [(212 − $t$) + 966 + 0.48 (T − 212)] ($t$ = temperature of air in the boiler-room, T = that of the flue gases). | | |
| 3. Loss due to moisture formed by the burning of hydrogen = per cent. of hydrogen to combustible ÷ 100 × 9 × [(212 − $t$) + 966 + 0.48 (T − 212)]. | | |
| 4.* Loss due to heat carried away in the dry chimney gases = weight of gas per pound of combustible × 0.24 × (T − $t$) | | |
| 5.† Loss due to incomplete combustion of carbon = $\frac{CO}{CO_2+CO} \times \frac{\text{per cent. C in combustible}}{100} \times 10{,}150$. | | |
| 6. Loss due to unconsumed hydrogen and hydro-carbons, to heating the moisture in the air, to radiation, and unaccounted for. (Some of these losses may be separately itemised if data are obtained from which they may be calculated) | | |
| Totals | | 100 |

*The weight of gas per lb. of carbon burned may be calculated from the gas analyses, as follows:

† $CO_2$ and CO are respectively the percentages by volume of carbonic acid and carbonic oxide in the flue gases. The quantity 10,150 = number of heat units generated by burning to carbonic acid 1 lb. of carbon contained in carbonic oxide.

$$\text{Dry gas per lb. carbon} = \frac{11CO_2 + 80 + 7(CO + N)}{3(CO_2 + CO)}, \qquad (68)$$

in which $CO_2$, CO, O and N are the percentages by volume of the several gases. As the sampling and analyses of the gases in the present state of the art are liable to considerable errors, the result of this calculation is usually only an approximate one. The heat balance itself is also only approximate for this reason, as well as for the fact that it is not possible to determine accurately the percentage of unburned hydrogen or hydrocarbons in the flue gases.

The weight of dry gas per lb. of combustible is found by multiplying the dry gas per lb. of combustible by the percentage of carbon in the combustible, and dividing by 100.

Digitized by Google

**419. Especial care should be taken to isolate the boiler tested** so that leakage can be eliminated or measured. No single valve may be considered absolutely tight. Where lines cannot be completely disconnected, there should be two closed valves with a half-inch open bleeder between them to indicate leakage. Variations of water level must be corrected for.

**420. Summary of overall results.**

| | Total Quantities | |
|---|---|---|
| 1. | Date of trial | |
| 2. | Duration of trial | hr. |
| 3. | Weight of coal as fired | lb. |
| 4. | Percentage of moisture in coal | per cent. |
| 5. | Total weight of dry coal consumed | lb. |
| 6. | Total ash and refuse | lb. |
| 7. | Percentage of ash and refuse in dry coal | per cent. |
| 8. | Total weight of water fed to the boiler | lb. |
| 9. | Water actually evaporated, corrected for moisture or superheat in steam. | lb. |
| 10. | Equivalent water evaporated into dry steam from and at 212°. | lb. |

For further details, see the standard code of the A. S. M. E.

**421. Quality of steam.** The percentage of **moisture** in the steam should be determined by the use of either a throttling or a separating steam calorimeter. The sampling nozzle should be placed in the vertical steam pipe rising from the boiler. It should be made of 0.5-in. pipe, and should be extended across the diameter of the steam pipe to within half an inch of the opposite side, being closed at the end and perforated with not less than twenty 0.125-in. holes equally distributed along and around its cylindrical surface, but none of these holes should be nearer than 0.5 in. to the inner side of the steam pipe. The calorimeter and the pipe leading to it should be well covered with felting.

**422. Superheating** should be determined by means of a thermometer placed in a mercury-well inserted in the steam pipe. The degree of superheating should be taken as the difference between the reading of the thermometer for superheated steam and the reading of the same thermometer for saturated steam at the same pressure, as determined by a special experiment, and not by reference to steam tables.

**423. Sampling the coal and determining its moisture.** As each barrow-load or fresh portion of coal is taken from the coal-pile a representative shovelful is selected from it and placed in a barrel or box in a cool place and kept until the end of the trial. The samples are then mixed and broken into pieces not exceeding 1 in. in diameter, and reduced by the process of repeated quatering and crushing until a fine sample weighing about 5 lb. is obtained and the size of the larger pieces is such that they will pass through a sieve with 0.25-in. meshes. From this sample two 1-qt., air-tight glass preserving jars, or other air-tight vessels which will prevent the escape of moisture from the sample, are to be promptly filled, and these samples are to be kept for subsequent determinations of moisture and of heating value and for chemical analyses. For further details, see the standard code of the A. S. M. E.

**424. Calorific tests and analysis of coal.** The quality of the coal should be determined either by heat test or by analysis, or by both. The rational method of determining the total heat of combustion is to burn the sample of coal in an atmosphere of oxygen gas, the coal to be sampled as directed in Article XV of the code. The **chemical analysis** of the coal should be made only by an expert chemist. The total heat of combustion computed from the results of the ultimate analysis may be obtained by the use of Dulong's formula (with constants modified by recent determinations), viz.,

$$14{,}600C + 62{,}000\left(H - \frac{O}{8}\right) + 4{,}000S, \qquad (68)$$

in which C, H, O, and S refer to the proportions of carbon, hydrogen, oxygen and sulphur, respectively, as determined by the ultimate analysis. It is desirable that a **proximate analysis** should be made, thereby determining

Digitized by Google

the relative proportions of volatile matter and fixed carbon. These proportions furnish an indication of the leading characteristics of the fuel, and serve to fix the class to which it belongs. As an additional indication of the characteristics of the fuel the specific gravity should be determined.

**425. Treatment of ashes and refuse.** The ashes and refuse are to be weighed in a dry state. If it is found desirable to show the principal characteristics of the ash, a sample should be subjected to a proximate analysis and the actual amount of incombustible material determined. For elaborate trials a complete analysis of the ash and refuse should be made.

**426. A throttling or a Thomas electric calorimeter** should be used where possible, in preference to separating or other types. **Thermometers** are more satisfactory as indicators of saturated steam pressure than spring gages.

**427. Engine testing** requires essentially: (a) Weight of steam used; (b) kw. output of generator, or brake h.p.; (c) i.h.p., from indicator cards; (d) rev. per min.; (e) steam pressure, receiver pressure and back pressure or vacuum; (f) quality of steam. Desirable additional data include: (g) receiver and exhaust temperatures; (h) weight of condensation from receiver or elsewhere; (j) reheater steam, if used.

**428. The steam consumption** is best obtained by weighing the discharge from a surface condenser; but if jet condensers are used or the engine is non-condensing, the feed water must be measured as it enters the boilers, the boiler leakage determined, and the boilers isolated from all other steam piping and apparatus. If the condensate is weighed, the condenser leakage must be ascertained. The test should continue not less than 1 to 3 hr., with surface condensers and 8 hr. when using the feed-water method.

**429. Turbine testing** involves the following essential data: (a) Steam weight per hr.; (b) initial and exhaust pressures; (c) superheat, or wetness of steam; (d) rev. per min.; (e) b.h.p. or kw. output of generators; (f) steam chest pressure. There is a general similarity to engine testing, the only real difference lying in the absence of indicator cards. In measuring the condensate, provision must be made for measuring also the gland-water, or steam for sealing purposes, which is not strictly chargeable to the turbine, since all the water, or all the heat is recovered.

**430. For full data on turbine testing** see the standard rules of the A. S. M. E.

**431. Condenser testing.** The condenser is the chief auxiliary requiring test: generally it is convenient to combine the condenser test with the engine or turbine test on the attached prime mover. The essential readings are: (a) vacuum at exhaust entry referred to standard barometer; (b) condensate weight per hr.; (c) circulating water temperatures at inlet and discharge; (d) hot well temperature. Additional desirable data include: (e) vacuum at hot well; (f) vacuum at dry vacuum pump; (g) temperatures, top and bottom of condenser; (h) temperature of dry air at pump; (j) Pitot or Venturi meter readings on circulating water; (k) temperature of circulating water at beginning and end of each pass; (l) volume of dry air removed per min. A separate test for leakage should be made before the operating test, and tests for salt may be made on the condensate during the operation, if salt water is employed as cooling water.

**432. Tests of boiler feed pumps** and circulating water or hot-well pumps, of the centrifugal type, require the following readings, for turbine-driven units: (a) weight of steam used per hr.; (b) steam and exhaust pressures; (c) quality of steam, or superheat; (d) suction and discharge heads; (e) weight of water pumped—by scales, tank or Pitot or Venturi tube readings, which are close enough for this work (weirs may be used for large pumps); (f) rev. per min.

**433. In testing direct-acting steam pumps,** indicator cards should also be taken.

**434. For tests of electric driven pumps,** readings (a), (b), and (c) in Par. **432** would be replaced by kilowatt readings on the motor.

**435. Tests on turbine-driven fans** for forced or induced draft require: (a) Steam used per hr.; (b) steam pressure and back pressure; (c) quality of steam or superheat; (d) Pitot static and dynamic readings on suitable

Digitized by Google

fan outlet; (e) rev. per min. For motor drive, kilowatt readings will replace (a), (b) and (c).

**436. Complete plants have what amounts to a continuous test** in their regular records, if properly kept. Coal is bought and paid for by weight and by analysis; and recording wattmeters give the output. For yearly figures the plant storage usually is not an important factor, as its amount is small compared to the total consumption; but for monthly figures, a survey of the coal stored is necessary. This is usually made by taking readings at predetermined points over the bunkers or storage space and calculating the volume of coal, allowing generally 50 lb. per cu. ft. for bituminous coal and 54 lb. per cu. ft. for No. 1, No. 2 or No. 3 buckwheat anthracite.

**437. The apparatus required for weighing water** is preferably made up of one or more sets of tanks on platform scales; the accuracy may be kept to 0.25 per cent. quite readily. Where less accuracy is required, 0.5 to 1.5 per cent., measurement by volume in a tank, or by Venturi meter, or V-notch weir, is suitable.

**438. For measuring the steam used,** the best method is by surface condensers (which may be made substantially tight), using scale tanks for weighing the condensate.

**439. For measuring temperature up to 900 deg. Fahr.,** mercury thermometers of 12 in. length are most convenient; they should be used in iron or brass wells, with a little mercury in the bottom of the cup, and the remainder filled with oil. For temperatures above 500 deg. Fahr., nitrogen-filled mercury thermometers must be employed. Care should be taken to ascertain the immersion for which the thermometer is calibrated. Resistance thermometers are now available, but are in general very much more expensive; their use is a convenience where there are several inaccessible readings to be taken, as all the resistance bulbs may be read from one galvanometer and bridge. For higher temperatures than 900 deg. Fahr., resistance thermometers or thermocouples should be used. For high furnace temperatures, radiation or optical pyrometers are best. (Sec. 3.)

**440. For pressure measurements,** the spring gage is convenient but usually inaccurate; for pressures up to 15 lb., mercury columns are far better. For steam pressure, the thermometer is a valuable and accurate means of getting results. If the steam is superheated, a thermometer in a pressure chamber separated from the steam main by a condensing coil, and suitably drained, will give correct readings of pressure. If gages are used, they should be carefully checked at the operating pressure, in position if possible, against a standard gage tester.

**441. Frequency of observations.** Observations of temperatures, pressures and speeds should occur once every 10 or 15 min. Water and coal weighings should be made as often as needed by the capacity of the containers on the scales. Wattmeter readings and coal and water readings should be balanced every hour, as a precautionary measure in checking the steadiness and reliability of the test. Calorimeter readings on boilers and turbines at steady load only need be taken at half-hourly or hourly intervals, as they vary but little. Barometer readings taken three times during a test are sufficient. For short tests, such as occur in motor-driven pumps and fans with Pitot tube or Venturi tube readings, instantaneous values taken once a minute for 10 min. gives good enough results as a rule. Pitot readings for air should be taken at numerous points in the pipe (see Treat, *Trans.* A. S. M. E., 1912, and Rowse, *Trans.* A. S. M. E., 1913, and Taylor, *Trans.* N. A. & M. E., 1905).

**442. Duration of tests.** Engine or turbine tests by the feed-water method should not be less than 8 hr., as the error introduced by variations of level in the boilers is too great on shorter tests; when weighing the condensate, 1 to 3 hr. will be sufficient, depending on reservoir capacity in the system. Where flow meters can be employed with sufficient accuracy, instantaneous tests of a few minutes duration may be run. The time taken for a boiler test, start to stop, should never be less than 10 hr., 12 are better and 18 to 24 hr. give much more consistent results. This length of time is needed on account of the variable error introduced by the unknown amount of coal on the fire at start and finish.

Digitized by Google

**443. Precision of tests.** Boiler tests of 10 hr. duration are seldom closer than 3 per cent. either side of the average; 12-hr. tests, 2.5 per cent.; 24 hr. 1 per cent. Engine tests of 8 hr. duration, will have a probable error of 2 per cent.. either way; turbine tests of 3 hr., 2 per cent. It is therefore needless to compute results closer than $\frac{1}{10}$ of 1 per cent.

# GAS POWER PLANTS

## BY REGINALD J. S. PIGOTT

### PRODUCERS

**444. Destructive distillation** can occur only with fuels containing volatile matter; therefore anthracite and coke producers cannot be said to operate by destructive distillation. **Gas** may be produced from **hard coal** as follows: with air only, $2C+O_2=2CO$; with steam only, $H_2O+C=CO+H_2$; with both steam and air, $3C+O_2+H_2O=3CO+H_2$. The first process is not often used; the second is used to make **water gas**, but since it does not produce heat, it is used intermittently with the process $C+O_2=CO_2$, or simple combustion of the fuel in the producer to generate the necessary heat. This is called "blasting up." The third process is the one used in making **producer gas** from anthracite or coke.

**445. With bituminous coals,** the volatile matter is given off as tar and hydrocarbon gases of the methane series, chiefly. These are again broken up by the heat in the producer to methane, carbon monoxide and hydrogen. In addition, the formation of CO and H from the coke remaining, goes on substantially as in the anthracite producer. In the down-draft types of producers, the tar passes through the fuel bed and is broken down to combustible gases and lampblack, some of which are burned in the passage.

**446. Suction producers** obtain a flow of air, steam and gas by means of a slight difference of pressure due to the pump action of the four-cycle gas engine on the charging stroke, or by an exhauster.

**447. Pressure producers** obtain a flow of gas, etc., by means of a pressure fan or blower for the air, or a boiler for the steam. A pressure producer is independent of the engine, and does not affect the capacity of the latter.

**448. Up-draft producers** are arranged with the steam and air admitted at the bottom and gas removed from the top; tar passes off with the gas and must be removed by scrubbers and purifiers.

**449. Gasification of Anthracite Coal** (R. D. Wood Co.)

| Process | Products | | |
|---|---|---|---|
| | Lb. | Cu. ft. | Anal. by Vol. |
| 80 lb. C burned to CO | 186.66 | 2,529.24 | 33.4 |
| 5 lb. C burned to $CO_2$ | 18.33 | 157.64 | 2.0 |
| 5 lb. vol. HC (distilled) | 5.00 | 116.60 | 1.6 |

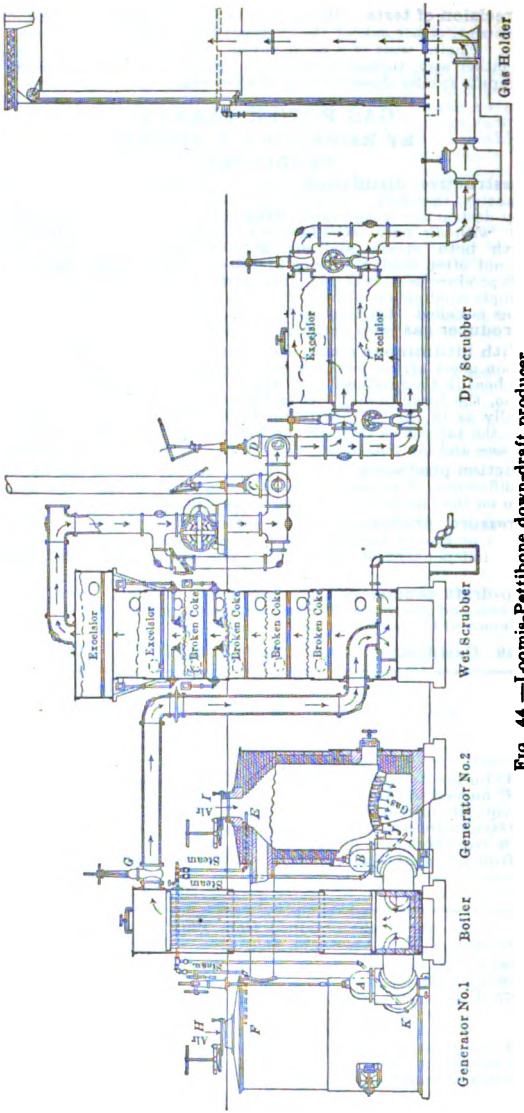

FIG. 44.—Loomis-Pettibone down-draft producer.

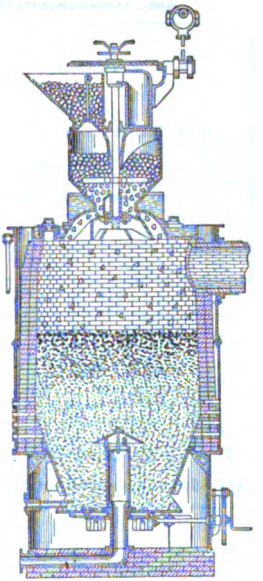
Digitized by Google

**450. Down-draft producers** are arranged with air and steam supply at the top, and gas removal under the firebrick grate at the bottom. The **double-zone producer** has down draft in the upper zone and up draft in the lower.

**451. Suction producers have the advantage** of not allowing gas to escape into the operating room from the producer, as the carbon monoxide is intensely poisonous; and poke openings, etc., can be conveniently operated. For small sizes, no exhaust fan is used, the necessary draft being provided by the engine suction. Most of the down-draft producers are suction types with exhaust fans. In this class belong the Loomis-Pettibone, De Lavergne, Körting, United Gas Machinery Co., Westinghouse double-zone, Otto, and Mond (small size).

**452. Pressure producers require forced draft** supplied by a fan or a steam jet blower, the steam thus admitted being used in the gasification. The tar formed is carried over with the gas and requires more extensive cleaning, but access to the grates is better than with the down-draft and suction types and mechanical stoking or poking may be employed either by mechanical water-cooled pokers, or by rotating the ash table and in some cases the producer shell. Examples of this type are the Mond large size, Taylor, and Chapman.

**453. The capacity of a producer** is based on 0.065 to 0.075 sq. ft. of cross-sectional area per brake h.p. of engine and about 0.105 to 0.118 cu. ft. of volume per h.p. (Snell).



*A*

FIG. 45.—Taylor or Mond up-draft producer.

**454. The continuous rate of gasification** with high-grade coal will not exceed 16 lb. of coal per hr. per sq. ft. of fuel bed; 10 lb. is a good average figure (Fernald, Bulletin 13, Bureau of Mines).

| 1,000 | ..... | ..... | ..... | 3 units 39 | 47 | 23–26 | 15,000 | 43 ft. |

Area depends of course on number and size of units for the total power given.

**458. The efficiency** of large producers will vary from 70 per cent. to 80 per cent. if the gases are used cold, and 80 to 90 per cent., if used hot (for furnace work). The losses include: (a) Sensible heat in gases; (b) producer radiation and conduction; (c) combustible in ash. The carbon in the ash of a properly operated large producer will be from 4 per cent. to 12 per cent. for about 0.5 to 1.5 per cent. total heat loss, with a coal having 10 per cent. to 12 per cent. ash. For small producers, suction type, the carbon in the ash may be as much as 60 per cent. of the total refuse, and the efficiency of the whole producer from 44 to 75 per cent. The sensible heat in the gases varies from 4 to 19 per cent., usually about 15 per cent. average.

**459. Heat balance.** The following data on the test of a Loomis-Pettibone producer were taken from the N. E. L. A. report on gas engines,

* Pressure plants exclusive of holder.

**462. Tests of Wood Pressure Producer**
(Gas plant test—24 days continuous running)

| *COAL | per cent. | GAS: Average | per cent. |
|---|---|---|---|
| Moisture | 14.68 | Carbon dioxide $CO_2$ | 9.2 |
| Volatile combustible | 30.98 | Oxygen $O_2$ | 0.0 |
| Fixed carbon | 42.93 | Ethylene $C_2H_4$ | 0.4 |
| Ash | 11.41 | Carbon Monoxide CO | 20.9 |
| | 100.00 | Hydrogen $H_2$ | 15.6 |
| Sulphur | 1.33 | Methane $CH_4$ | 1.9 |
| | | Nitrogen $N_2$ | 52.0 |

Calorific power 12,343 B.t.u. per lb. of dry coal.
Average heat value of gas for 24 days = 156.1 B.t.u. per cu. ft.

On the average of the Government tests generally Prof. Fernald gives the following:

**463. Tests by Geological Survey**

| Load 90—100 Per cent. 30 to 50 hr. | Bituminous | | Lignites | | Peat | |
|---|---|---|---|---|---|---|
| | As fired | Dry | As fired | Dry | As fired | Dry |
| B.t.u. per lb. of fuel | 12,280 | 13,150 | 8,350 | 11,290 | 8,127 | 10,289 |
| Cu. ft. of gas per lb. | 60.5 | 64.7 | 35.8 | 45.7 | 30.3 | 38.3 |
| B.t.u. per cu. ft. of standard gas. | 152.1 | ..... | 158.4 | ..... | 175.2 | ..... |
| Total lb. per b.h.p. hr. | 1.36 | 1.26 | 1.99 | 1.68 | 2.57 | 2.03 |

**464. Quantity of gas per lb. of fuel** in up-draft pressure producers is given in Par. **462** (Fernald, Tech. Paper No. 9, Bur. Mines., 1912).

**465. The addition of excess steam** over that theoretically required, if not too large, has little or no effect on efficiency, but gives more control over clinker formation. The steam required at 30 to 60 lb. gage is 0.33 to 2.5 lb., averaging 0.7 to 1.0 lb., per b.h.p. The highest figures are for by-product recovery plants.

**466. Analyses of gas** are given in Par. **128, 459, 460,** and **463.**

**467. The operation of gas producers** presents three main features: (a) maintenance of uniform resistance of bed, which includes regulation of feed and poking; (b) removal of ash; (c) prevention of clinker. In the case of up-draft producers coal is fed usually by an air-lock device and spreader; poking is done through holes in the top, to fill up holes or channels which may have formed by clinkering and arching, or by localized combustion. Poking must be carefully done to avoid starting the evils it is intended to correct. A moderate rate of driving will tend to keep fires in better condition, as the producer cannot be forced to the same extent as a boiler and give satisfactory results. The down-draft producer can be poked in the same manner as the suction producer.

**468. The cost of producers** ranges as follows:

Suction producers, up to 300 h.p., total cost $= 252 + 14.2 \times (\text{h.p.})$ (69)

Pressure producers, up to 300 h.p., total cost $= 860 + 15.15 \times (\text{h.p.})$ (70)

The foregoing figures were given by A. A. Potter, *Power*, 1913, p. 938. R. H. Fernald (Bull. 55, Bur. mines) gives values averaging, for producers of both types:

Total cost $= 250 + 9.70$ b.h.p. for sizes from 15 to 300 h.p. (71)

Repairs and maintenance vary from $0.15 to $0.25 per h.p. per year. Guarantees on maintenance are usually 2 to 3 per cent. of first cost a year.

* Prof. R. H. Fernald.

## SUPERHEATERS AND CONDENSERS

**469. The laws of heat transfer** for superheaters have been covered in Par. **15** to **29**, and for economizers in Par. **320**, for vaporizers in Par. **2, 3** and **4.**

**470. Superheaters** are attached to the vaporizers of some types of producer, to superheat the steam fed to the fuel bed. They are usually of the protected type, heated by the hot gas leaving the producer, and delivering superheated steam for use in the fuel bed. Some additional economy is gained by their use.

**471. Wash boxes** are water seals and serve the purpose of a check valve to prevent blowing back of gas. They are made of cast iron generally, with a cross-section equal to about 25 times the delivery pipe. The submersion of the entering pipe is about 3 in.

**472. Economizers** are employed for preheating the air fed to the producer and operate on the sensible heat of the gas leaving the producer.

**473. Vaporizers** or boilers are attached to nearly all producers, and serve to yield the necessary steam for gasification, abstracting sensible heat from the hot gas. They are usually built much like a vertical fire-tube boiler, or of cast-iron cooling chambers forming the top or side, of the producer.

**474. Condensers** are employed to remove the tar, and consist usually of chambers with iron baffles upon which the viscous tar impinges and collects; suitable drainage allows the tar to be recovered and removed. The general design is similar to an oil separator. Some are made with helical passages to secure centrifugal action. There are also one or two designs of mechanical tar extractors built like centrifugal fans, to throw out the tar by centrifugal force. They are generally made entirely of cast-iron.

**475. Operation.** The operation of superheaters requires practically no labor; vaporizers in this respect are the same as boilers; **tar separators** require periodic cleaning and continuous drainage. The tar is inclined to accumulate and thicken with the dust in the gas. The standby period for lignite or bituminous producers is from 6 to 10 hr. a week for cleaning purposes and repairs, on the average. Anthracite producers may be run 60 to 90 days continuously. (Latta, 1910.)

**476. The cost of these auxiliaries** is included in the cost of the producer, given in Par. **468**, since they are essential to operation.

## SCRUBBERS AND PURIFIERS

**477. The impurities found in producer gas** are dust, tar and ammonia. Dust is blown over from the fuel bed, being usually the ash from the fines in the coal. In some cases, lampblack is also carried over in the down-draft and double-zone types. Tar is the result of partial decomposition and is a combustible material. Ammonia is produced by the union of H dissociated in the producer with N in the air supplied.

**478. Two methods of cleaning** are used; (a) wet scrubbing, with stationary towers and water spray in some form, or mechanical scrubbers more or less like fans with water injection; (b) dry scrubbing, with purifiers or filters made with excelsior or shavings, which require periodic removal and cleaning.

**479. Wet scrubbers** consist of steel towers filled with coke, wire netting or wood latticing, somewhat after the fashion of a cooling tower. Water is sprayed down from the top, and divides into fine streams or spray, washing out solid impurities and tar, dissolving out ammonia and sulphur gases. The amount required varies from 1.5 gal. to 2.5 gal. per b.h.p. per hr.

**480. The mechanical washers** are chiefly heavy-built fans with water spray devices, or Theisen washers. The simple fan washer consists of centrifugal fans of heavy construction, usually with cast-iron casing, with a water spray device at the inlet to produce a spray curtain or fog through which the gas passes. The efficiency averages about 12 to 1, gas containing 1.75 to 2.65 gr. per cu. ft. being cleaned to 0.15 to 0.22 gr. per cu. ft. The h.p.

Digitized by Google

required per 1,000 cu. ft. per hr. is 0.066. With two fans in series, the cleaning is from 50 to 1, to 200 to 1 and the h.p. required is 0.184 to 0.283 per 1,000 cu. ft. per hr. The water required per fan is 0.0125 to 0.0150 gal. per cu. ft. cleaned per hr.

**481. The Theisen washer** consists of three elements in one casing: (a) a primary cleaning fan at the suction end; (b) an annular chamber between a drum fitted with helical vanes and a coarse mesh grating surrounding the drum; (c) a discharge fan chamber. Water spray is fed in at the suction chamber and tangentially in the grating. The water consumption is 0.0272 gal. per 1,000 cu. ft. per hr.; the h.p. required is 0.184 per 1,000 cu. ft. per hr. cleaned.

**482. The by-products recovered** from bituminous coal gasification are ammonium sulphate and tar. The recovery of ammonium sulphate requires the addition of an acid tower, through which dilute sulphuric acid is circulated as in a purifier. The acid removes the ammonia gas as ammonium sulphate. Tar is removed by separators or condensers, and may be used as a fuel in certain oil engines; it usually contains considerable moisture—up to 20 per cent., on account of the water employed in washing the condenser trays.

**483. Purifiers or dry scrubbers** consist of a steel tank or tower, filled with shavings, excelsior, coke, or Laming composition. Laming composition is a mixture of bog iron ore and shavings. It is used in 6-in. to 8-in. layers, on gratings, and absorbs cyanides and sulphur compounds. The Laming mixture is removed and exposed to the air from time to time, which regenerates the materials for use again. Shavings and other mechanical dry purifying material must be removed and replaced by fresh material as often as they become clogged. Wet scrubbers are automatically cleaned by the water used to precipitate dust.

**484. Cost of the apparatus** is included in the cost of producers, Par. 468.

## HOLDERS

**485. Gas storage** is required to provide reserve capacity for sudden increase of demand, and to absorb excess generation when sudden decrease of load occurs.

**486. The holder** is of the regular collapsing gasometer type, in no way different from the ordinary illuminating- as tank. In some cases the water seal in the base is used as an additional wash-box for incoming producer gas.

**487. The capacity required** varies from 40 to 25 cu. ft. up to 100 h.p.; 20 to 15 cu. ft. up to 1,000 h.p. The larger the number of units the less storage usually required, as manipulation is more flexible.

**488. The operation of gas holders** requires only occasional painting to protect the tank, yearly cleaning of sediment from the water reservoir, and suitable steam-supply to the lift seals to prevent freezing in winter.

**489. The cost of gas-holders** varies from $0.60 to $0.45 per cu. ft. including foundations.

## PROPERTIES OF GAS

**490. Calorific Value of elementary gases.** (From Gas Engine Design —Lucke.)

| Fuel | B.t.u. per lb. | | Lb. per cu. ft. at 62 deg. fahr. | B.t.u. per cu. ft. | |
|---|---|---|---|---|---|
| | High | Low | | High | Low |
| H..... | 61,524.0 | 51,804.0 | .00538 | 331.0 | 278.7 |
| CO..... | 4,395.6 | 4,395.6 | .07498 | 329.58 | 329.58 |
| $CH_4$..... | 24,021.0 | 21,592.8 | .04308 | 1,037.22 | 932.38 |

Digitized by Google

**491. Producer gas** has a specific gravity, referred to air, of 0.97, average specific heat, 0.25. It varies in composition, not only with the type of producer, but from variations in operation of the same producer. The hydrogen content, being usually high, limits the compression, usually from 100 to 160 lb. per sq. in., with 18 to 5 per cent. of hydrogen, average pressure 135 lb. Careful jacketing of valves and pistons for large engines raises the obtainable compression.

**492. Natural gas** is the richest of the power gases, and is obtainable chiefly through the soft coal and oil regions. Ohio, Indiana, Illinois, Pennsylvania and Virginia are most favored in this way. The allowable compression varies from 75 to 130 lb. The specific gravity referred to air is approximately 0.40 to 0.50; density, 0.043 to 0.049 lb. per cu. ft.

**493. Illuminating gases,** either coal or water gas, are usually too expensive for use in any but the smallest engines, up to say 75 h.p. The allowable compression is 60 to 100 lb. average 80; specific gravity approximately 0.40 to 0.43 for coal gas, 0.57 for water gas.

**494. Blast-furnace gas** is the leanest of the gases and will stand compression from 120 to 190 lb., averaging 155 lb.; this is on account of the dilution with N, and low hydrogen. It is used only in large gas engines at steel mills.

## GAS ENGINES

**495. Gas-engine cycles.** The thermodynamics of the gas engine is complicated by the fact that not only the change of state by expansion and compression occurs in the cylinder, but also the combustion. The order of events in the usual Otto or **four-stroke cycle** is as follows: aspiration of a charge into the cylinder (suction stroke); compression, approximately adiabatic on the instroke; ignition and explosive combustion at constant volume, while the piston is on or near the dead centre; and approximately adiabatic expansion on the second outstroke; partial expulsion of the burnt gases at constant volume when on the outer dead center, further expulsion on the second instroke, at atmospheric pressure. **The two-stroke cycle** eliminates the suction and exhaust strokes, by admitting the incoming charge under a few pounds pressure while the piston is on or near the outer centre, after the partial exhaust to atmospheric pressure and constant volume has just taken place. This incoming charge sweeps before it, by displacement, most of the remaining burnt gases.

**496. The standard reference diagram** put forward by Lucke is useful in investigating the performance or design. This diagram is an assumed indicator card based on the assumption that the mixture in the cylinder will behave the same as pure air. The general relations are as given below.

**497. Compression pressure.**

$$p_b = p_a\left(\frac{v_a}{v_b}\right)^{1.41} \quad \text{and} \quad t_b = t_a\left(\frac{v_a}{v_b}\right)^{1.41} \tag{72}$$

where $p_a = 14.7$ lb. per sq. in., suction pressure; $p_b$ = final compression pressure; $v_a$ = total cylinder volume in cu. ft. = displacement plus clearance; $v_b$ = compression volume, or clearance, in cu. ft.; $t_a$ = absolute initial temperature (deg. Fahr. + 461); and $t_b$ = absolute compression temperature.

**498. The pressure rise on explosion** depends on the amount of heat per cu. ft. of mixture.

$$p_c = p_b\left(\frac{Q}{C_v t_b} + 1\right) \quad \text{and} \quad t_c = t_b + \frac{Q}{C_v} \tag{73}$$

where $p_c$ = explosion pressure; $Q$ = B.t.u. per lb. of mixture; $C_v$ = specific heat at constant volume; $t_c$ = absolute explosion temperature; and the other symbols are as above (Par. **497**).

$$p_c - p_b = \frac{2.2\ Q}{\left(\frac{p_a}{p_b}\right)0.71\ v_a} \text{ (in lb. per sq. in.)} \tag{74}$$

**499. B.t.u. per cu. ft.**

$$\frac{Q}{v_a} = \frac{H}{n + a' + 1} \tag{75}$$

Digitized by Google

where $H$ = B.t.u. per cu. ft. of mixture, hot; $a'$ = cu. ft. of air required to burn 1 cu. ft. gas; and $n$ = cu. ft. of neutral added. The actual pressure ratio $p_c/p_s$ obtained is from 40 per cent. to 65 per cent. of the air card ratios.

**500. Expansion** is taken according to the law

$$p_d = p_c\left(\frac{v_c}{v_d}\right)^{1.41} \tag{75}$$

which is the same as for compression.

**501. Efficiency.**

$$E = 1 - \frac{t_a}{t_b} = 1 - \left(\frac{p_a}{p_b}\right)^{0.29} \tag{77}$$

where $E$ = thermal efficiency of the cycle; other symbols are as above. The thermal efficiency of the ideal cycle is only dependent upon the ratio of compression to suction pressure.

**502. Four-cycle engines** are built in all sizes; the terms single and double acting have the same application as for steam engines. The majority of engines of small and moderate size are single acting. Large engines are generally made double acting, to economize space, as the gas engine is even more bulky per h.p. than the steam engine.

**503. Two-cycle engines** are also used in all sizes, but are found to the greatest extent in large units, double acting. For small units they are never built double acting, as separate pumps are then required to give the pressure for charging at the end of each stroke. In the small single-acting types, the mixture is compressed between the piston and the crank case.

**504. Cylinder jackets** are essential to practically all gas engines. The enormous heat developed during explosion would soon destroy the cylinder and piston if they were not protected by cooling. In most cases this is done by **water jacketing**; in a few small engines, **air cooling** is employed. Pistons smaller than 15 in. in diameter are not separately cooled by water jacketing; but above this size, the area of piston head is too large to be properly cooled by conduction to the jacketed cylinder walls, and the air in the crank case; therefore water cooling becomes necessary.

**505. The quantity of jacket water** should be about 6.5 gal. per b.h.p.-hr. at 50 deg. Fahr., 7.75 gal. per b.h.p.-hr. at 60 deg. Fahr., 9.75 gal. per b.h.p.-hr. at 70 deg. Fahr., and 12 gal. per b.h.p.-hr. at 80 deg. Fahr., for large units. Most of this may be recovered and re-used if cooled. If a cooling tower is used, for recooling the jacket water, about 8 per cent. is lost by evaporation. The heat loss to the jacket is from 25 to 50 per cent., generally the largest with small engines.

**506. Mean effective pressure** is computed from the indicator card in the same manner as for a steam engine. The m.e.p. of the reference diagram is given by

$$\text{M.e.p.} = \frac{5.41Q}{(v_a - v_b)}\left\{1 - \left(\frac{p_a}{p_b}\right)^{0.29}\right\} \tag{78}$$

or

$$\text{M.e.p.} = 5.41\left(\frac{H}{a'+1}\right)\left\{1 - \left(\frac{p_a}{p_b}\right)^{0.29}\right\} = C\left(\frac{H}{a'+1}\right) \tag{79}$$

where the symbols have the same meaning as in Par. **497** to **500**.

For constants to be used with these equations see Par. **507**.

**507. Constants used in Calculation of M.E.P. (Par. 506)**

| Compression | | Value of factor $C = 5.41 \times 1 - \left(\frac{p_a}{p_b}\right)^{0.29}$ | Compression | | Value of factor $C = 5.41 \times 1 - \left(\frac{p_a}{p_b}\right)^{0.29}$ |
|---|---|---|---|---|---|
| Atmospheres | Lb. per sq. in. | | Atmospheres | Lb. per sq. in. | |
| 3 | 44.1 | 1.474 | 8 | 117.6 | 2.446 |
| 4 | 58.8 | 1.787 | 9 | 132.3 | 2.554 |
| 5 | 73.5 | 2.014 | 10 | 147.0 | 2.630 |
| 6 | 88.2 | 2.187 | 11 | 161.7 | 2.711 |
| 7 | 102.9 | 2.327 | 12 | 176.4 | 2.775 |

Digitized by Google

**508. Observed mean effective pressures** obtained by test are given by Lucke:

| Fuel | Compression, lb. per sq. in. abs. | M.e.p. actual lb. per sq. in. | Fuel | Compression, lb. per sq. in. abs. | M.e.p. actual lb. per sq. in. |
|---|---|---|---|---|---|
| City gas..... | 45 | 45 | Producer gas.. | 103 | 63 |
| | 60 | 80 | | 108 | 88 |
| | 66 | 95 | | 125 | 51 |
| | 91 | 90 | | 141 | 83 |
| | 70 | 60 | | 170 | 73 |
| | | | | 95 | 100 |
| Natural gas ... | 127 | 68 | | 95 | 90 |
| | 130 | 82 | | 90 | 62 |
| | 135 | 90 | | 115 | 103 |
| | | | Blast-furnace gas..... | ..... | 60 |
| | | | | 140 | 47 |
| | | | | 155 | 81 |

**509. The ignition** of gas engines is practically entirely electric. The jump-spark or high-tension spark system is not used for power-station engines. Make-and-break systems are used, because more reliable and effective. The principal troubles are insulation breakdowns, worn and dirty contacts or short-circuiting by jacket leaks.

**510. The timing of ignition** affects the work done by a given charge and the economy. Ignition should take place so as to give a nearly vertical explosion line. The spark should be advanced, theoretically, as the rate of propagation is decreased by weakening the mixture or the compression, but in practice the spark is usually fixed to give the best results at the average load condition, and is not varied.

**511. The speed of gas engines** is about the same as for steam engines of the same class. See Par. **170**. In small engines the speed may be 10 to 25 per cent. higher.

**512. Indicated horse-power** is obtained in the same manner as for steam engines, except that care must be used in planimetering the card to go around the negative work areas in the right direction. For throttle governed engines, the number $N$ in formula 34a, is the same as rev. per min. for 2-cycle engines and rev. per min./2 for 4-cycle engines; with engines governed by the hit-and-miss method, the number of explosions must be counted to get $N$, as it has no fixed relation to rev. per min.

**513. The friction** is usually higher in the gas engine than in the steam engine; the mechanical efficiency at full-load is seldom over 85 per cent., even for large engines. Lucke gives.

| | Mech. Efficiency | |
|---|---|---|
| | 4-cycle | 2-cycle |
| Large engines, 500 h.p. and over..... | 0.81 to 0.86 | 0.63 to 0.70 |
| Medium, 25 to 500 h.p..... | 0.79 to 0.81 | 0.64 to 0.66 |
| Small, 4 to 25 h.p..... | 0.74 to 0.80 | 0.63 to 0.70 |

**514. Lubrication** is entirely by machine oil, as the cylinder walls are water cooled. Lubrication in general is handled exactly as with the steam engine. About 1 gal. of oil is required per 4,000 b.h.p.-hr.

**515. The rated capacity** of a gas engine is preferably based on cu. ft. of cylinder displacement. The displacement per h.p. per lb. of mean effective pressure is 229.17 cu. ft. per min. For a given b.h.p. required, the mechanical efficiency is assumed and the i.h.p. found; and with a suitable

Digitized by Google

m.e.p. for the fuel employed (Par. **506**), the required displacement per h.p. divided into required i.h.p. gives total cylinder displacement per minute: Internal combustion engines are usually rated at 15 per cent. to 20 per cent. below the capacity of the cylinder as given above. Torrance and Ulbricht (*Power*, 1912) give the following **formulæ for builders' rating** in America.

$$\text{Producer gas, b.h.p.} = \frac{d^2ln}{18{,}500} - 2.0 \qquad (80)$$

$$\text{Illuminating gas, b.h.p.} = \frac{d^2ln}{15{,}700} - 2.0 \qquad (81)$$

$$\text{Natural gas, b.h.p.} = \frac{d^2ln}{15{,}200} - 5.0 \qquad (82)$$

$$\text{Blast-furnace gas, b.h.p.} = \frac{d^2ln}{21{,}000} - 5.0 \qquad (83)$$

where $d$ = diameter of cylinder, inches; $l$ = stroke in inches; and $n$ = rev. per. min.

**516. The fuel consumption** of gas engines on producers ranges from 0.99 to 3 lb. per b.h.p.-hr. From 75 to 90 cu. ft. of gas per b.h.p.-hr. are required, of approximately 150 B.t.u. per cu. ft.

**517. Test of 300-h.p. Illmer 2-stroke cycle double acting horizontal engine.** (*Power*, May, 1913.) Duration of test, 33.5 hr.; coal, Westmoreland bituminous, 14,100 B.t.u. as fired; average b.h.p., 284; average B.t.u. per cu. ft. of gas, 144; Producer efficiency, 67 per cent.; B.t.u. per h.p.-hr., 10,300; total coal per b.h.p.-hr. 1.14.

**518. Fuel consumption,** Ulbricht and Torrance (Power, 1912) give average fuel consumption as below: (B.t.u. and cu. ft. per h.p.-hr.)

| | 50 b. h.p. | | | 100 b.h.p. | | | Over 100 b.h.p | | |
|---|---|---|---|---|---|---|---|---|---|
| | B.t.u. | cu.ft. | Eff. | B.t.u. | cu. ft. | Eff. | B.t.u. | cu. ft. | Eff. |
| Water gas..... | 10,690 | 35.2 | 23.8 | 10,160 | 33.4 | 25.0 | 10,160 | 33.4 | 25.0 |
| Carburetted gas. | 10,690 | 18.1 | 23.8 | 10,160 | 17.2 | 25.0 | 10,160 | 17.2 | 25.0 |
| Coal gas..... | 10,690 | 17.6 | 23.8 | 10,160 | 16.7 | 25.0 | 10,160 | 16.7 | 25.0 |
| Producer gas: | | | | | | | | | |
| anthracite.... | 10,380 | 82.6 | 24.5 | 9,630 | 76.6 | 26.4 | 9,600 | 76.3 | 26.5 |
| bituminous... | 10,380 | 83.0 | 24.5 | 9,630 | 77.0 | 26.4 | 9,600 | 76.7 | 26.5 |
| coke..... | 10,380 | 82.0 | 24.5 | 9,630 | 76.2 | 26.4 | 9,600 | 76.0 | 26.5 |
| lignite..... | 10,380 | 77.5 | 24.5 | 9,630 | 71.8 | 26.4 | 9,600 | 71.6 | 26.5 |
| oil..... | 10,380 | 68.7 | 24.5 | 9,630 | 63.7 | 26.4 | 9,600 | 63.5 | 26.5 |
| peat..... | 10,380 | 73.6 | 24.5 | 9,630 | 68.3 | 26.4 | 9,600 | 68.0 | 26.5 |
| wood..... | 10,380 | 80.6 | 24.5 | 9,630 | 74.8 | 26.4 | 9,600 | 74.6 | 26.5 |
| Blast-furnace gas | 10,860 | 114.0 | 23.4 | 10,500 | 110.0 | 24.2 | 9,860 | 104.0 | 25.8 |
| Coke-oven gas.. | 10,690 | 22.0 | 23.8 | 10,160 | 20.9 | 25.0 | 10,160 | 20.9 | 25.0 |
| Natural gas avg.. | 10,380 | 12.2 | 24.5 | 9,420 | 11.0 | 27.0 | 9,320 | 10.9 | 27.3 |

**519. Test of a 310-h.p. engine,** horizontal double-acting (Buckeye), running on coke-oven gas, 560 B.t.u. per cu. ft., gave the following results.

| Load | B.h.p. | B.t.u. per h.p. hr. | Per cent. efficiency |
|---|---|---|---|
| ½ | 165 | 13,000 | 18.5 |
| ¾ | 210 | 11,700 | 23.0 |
| full | 310 | 11,100 | 22.5 |

The B.t.u. per kw.-hr., with blast-furnace gas engines (Freyn, 1913), varies from 16,200 to 26,000, average 18,400; thermal efficiency 13.0 to 21.0 per cent., average 18.5.

**520. Test of a 500-h.p. engine** of the Borsig-Oechelhäuser 2-cycle type, on coke-oven gas (Junge, in *Power*) gave results as follows:

Digitized by Google

| I.h.p. | B.t.u. per b.h.p. | Per cent. of i.h.p. to pumps | I.h.p. | B.t.u. per b.h.p. | Per cent. of i.h.p. to pumps |
|---|---|---|---|---|---|
| 616 | 8,650 | 10.3 | 488 | 9,642 | 14.2 |
| 627 | 8,650 | 11.1 | 474 | 9,761 | 15.5 |
| 574 | 8,650 | 11.4 | | | |

**521. Test of a 600-h.p. engine,** Körting 2-cycle type, gave these results: b.h.p. 616; pump work, 11.2 per cent. of total; mechanical efficiency, 0.78; lb. of coal per b.h.p-hr., 0.787.

**522. Thermal efficiency** of gas engines is given in Par. **518** and **519** in connection with some of the tables. Further data is given as follows by Diederichs:

| Engine | Fuel | B.h.p. | Thermal efficiency | Authority |
|---|---|---|---|---|
| Otto..... | Illuminating gas..... | 8 | 29.4 | Meyer |
| Deuts..... | Suction producer, low grade soft coal. | ..... | 22.4 | Meyer |
| Nürnberg... | Blast-furnace gas..... | 750 | 24.6 | Linde |
| Deuts..... | Anthracite producer..... | 450 | 22.0 | Josse |
| Güldner.... | Suction anthracite producer. | 29 | 23.2 | Schroter |

**523. The overload capacity** (Par. **515**) is generally 10 to 20 per cent. more than the rated capacity. The maximum capacity is limited by the dimensions of the cylinder and not by a variable cut-off. Maximum economy occurs at or near, maximum capacity.

**524. Governing** is accomplished by hit-or-miss, throttling or quality methods. **Hit-or-miss governing** is arranged with a movable pick-blade operating the gas inlet valve; it is now used only for low-grade agricultural engines. **Throttle governing** is employed on a great many engines of small and medium size, and consists simply of restricting both the gas and the air intakes, so that the suction stroke pressure is lowered, a smaller charge is taken in, and compression is reduced. **Quality or cut-off governing** consists of throttling the gas supply only, as the load drops. In this way no reduction of suction pressure occurs, but a reduction of gas in the charge only. The compression pressure is unaltered. This method is the best of the three, being more efficient at light load than throttling, and allowing better regulation than hit-or-miss.

**525. Operation of a gas engine** requires the same care as a steam engine, and a higher maintenance. Power-station gas engines are started by compressed air in most cases, although motor starters have been employed. Special valve gear is thrown into service, and the engine runs for a revolution or two as an air engine. **Before starting,** (a) the load must be off, (b) ignition system inspected and made ready in the retarded position, (c) lubricating oil feeds turned on, (d) fuel shut-off valve opened and (e) cooling water turned on. Failure to start may be due to (a) faulty ignition, (b) very abnormal mixture, either too rich or too lean, (c) broken valve rods or (d) closed fuel connections. **Ignition** should be adjusted to give a fairly sharp rise at the average load conditions, and the mixture should be a little leaner than theoretical proportions—say 15 to 20 per cent. **Shutting down** is best accomplished by, (a) cutting off fuel supply, (b) cutting out ignition, if on battery, and placing set in "retarded" position, (c) oil feed stopped, (d) cooling water shut off and jackets drained.

**526. The cost of gas engines** is given by Fernald (Bull. 55, Bureau of Mines).

Total cost = 250 + 34.8(b.h.p.), for 40 h.p. to 2,000 h.p. (84)

A. A. Potter (*Power*, 1913) gives, for engines of 50 to 300 h.p., on illuminating gas. Total cost = 33.6 × b.h.p. − 115. (85)

Digitized by Google

The following figures are given by Stott, Pigott and Gorsuch, *Transactions* A.I.E.E., June, 1914. Horizontal producer-gas and natural-gas engines, 4-cycle tandem and twin-tandem, direct connected to 60-cycle generators, 200–2,000 kw. @ 80 per cent. power-factor delivered and erected.

$$\text{Average total cost} = 2{,}000 + 70\ (\text{kw.}) \qquad (86)$$

**527. The maintenance and repair costs** are approximately 42 per cent. to 55 per cent. of the net operating cost. For oil and supplies the cost is about double that of a steam plant.

**528. Weight.** The net weight of large tandem double acting types averages 680 to 740 lb. per kw. Moderate sizes of single-cylinder, single acting engines weigh from 200 to 300 lb. per b.h.p., the unit weight going up with the b.h.p.

## PIPING

**529. General requirements.** As all pressures are light, standard pipe and fittings may be used throughout. **Expansion** must be provided for in the same manner as steam piping (Par. 369 to 372).

**530. Gas piping** from producer to scrubbers and purifiers should be cast iron with standard flanged joints, asbestos or metallic packing. In most cases it is advisable to line the piping between scrubber and producer with fire-brick. Explosion doors should be installed at intervals, and if the gas is dusty, ells should be replaced by tees where possible, to provide for raking and cleaning.

**531. Water piping** for supply to jackets, vaporisers and purifying apparatus may be of ordinary galvanised standard pipe. The discharge from scrubbers and purifiers is preferably of cast iron, on account of corrosive action.

**532. Exhaust piping** can be built of wrought-iron standard pipe, or cast-iron standard pipe; light riveted pipe is not advisable as it may collapse on the return wave of a muffler or exhaust pipe explosion. **Mufflers** for small engines are usually cast-iron pots; for large plants, concrete tunnels, with water in the bottom to cool and silence the exhaust, are frequently used.

**533. The cost of piping** varies from $5 to $9 per kw. of maximum rating of the plant, being much the same as for steam plants.

## PLANT ECONOMY AND DESIGN

**534. The auxiliaries** to be considered in the engine room are: compressors for starting; exciter units and cooling water pumps; station lighting. In the producer room the auxiliaries are: the blowers or exhausters, as the case may be; power for rotating ash table, producer body, or mechanical pokers, if these are used; coal and ash handling apparatus; mechanical washers and tar extractors; scrubber and washer water-supply pumps.

**535. The heat losses in a producer plant** will be indicated by the following analysis. (Snell, "Power House Design.") Loss in producer and auxiliaries, 20 per cent.; loss in jacket water, 19 per cent.; loss in exhaust gases, 30 per cent., loss in engine friction, 6.5 per cent., loss in generator 0.5 per cent., total losses, 76 per cent., converted to electrical energy, 24 per cent.

**536. The Willans line** for the several main units should be plotted with kw. output and cu. ft. of gas as ordinates. On this curve should be superposed the gas used by auxiliaries, or if these are electric driven, their requirements should be subtracted from the gross output of the generators before plotting the Willans line. By taking the gas required at any load from this curve, and plotting for the load curve of the plant, the gas demand of the engine room is obtained. Similarly, an input-output curve for the producer can be drawn, between coal fired and gas generated; on this is superposed the gas or power demands of producer room auxiliaries and the standby coal. In conjunction with the engine-room gas demand curve, this gives the coal demand for the station under load.

**537. Power for auxiliaries.** The power required for the blower or exhauster will be from 1 to 2.5 per cent. of the total horse-power of the producer.

Digitized by Google

The horse-power requirements of washers are given in Par. **480**. The coal and ash handling system will not usually require more than 0.2 to 0.4 per cent. of the total horse-power; compressor equipment, not over 0.1 per cent. The total power requirements of the auxiliaries will be about 5 per cent. The **standby losses** of a producer banked 14 hr. in 24 are about 1.5 to 2.0 per cent. of the total.

**538. Water consumption per h.p.**, for the plant will run from 5 to 8 lb. per kw-hr., at the switchboard for non-recovery plants, and 40 lb. per kw-hr. for recovery plants, using cooling towers in both cases.

**539. Vertical vs. horizontal engines.** Design practice in plants up to 2,000 b.h.p. will allow vertical engines; these usually are not built over 750 to 1,000 h.p. per unit. Above this size only horizontal engines are used.

**540. Ammonia recovery.** It is not worth while to attempt the recovery of ammonia from bituminous plants of less than 2,000 b.h.p., and then only when the load factor is above 25 per cent. Each ton of coal produces approximately 100 lb. of sulphate of ammonia; the sulphuric acid required is about 1 to 1 in weight ratio to the sulphate of ammonia. In cities, the recovery plant is practically out of the question on account of space requirements. Extra labor, the acid tower, extra repairs and the cost of bagging the sulphate must be taken into account.

**541. The floor space** required is from 5 to 8 sq. ft. per kw., or 3 to 4 times the floor space for a turbine plant. The producer room requires from 2.5 to 4 sq. ft. per kw.

**542. The load factor** should be high for a successful gas plant. The gas engine is not well suited for heavily swinging loads partly on account of its lack of much overload capacity.

**543. The subdivision of generating units** should be the same as for a steam plant—six to eight units if possible. For small units, up to 400 b.h.p. one reserve unit in 5 or 6 is sufficient; but for large units (which have never been brilliantly successful), one in four is necessary for continuity of operation. The **reliability** of the gas engine is still open to much question in very large units, but the units of moderate and small size are as reliable as steam engines, if given the same grade of attention.

**544. Labor required** is usually one man per engine above 750 h.p. and one man to four or five producers of good size and equipped with mechanical apparatus for feed and stoking. About one man for 1,000 to 1,200 h.p. of engine, and one man per 2,000 to 2,500 h.p. of producer, represent the average.

**545. Total plant cost.** The following data is taken from the 1909 report of the N. E. L. A. on gas power plants.

360 to 2,700 kw. maximum rating

| Item | Dollars per kw. | | |
|---|---|---|---|
| | Maximum | Minimum | Average |
| Building | 44 | 16 | 33 |
| Producer equipment incl. piping | 49 | 33 | 38 |
| Gas engines | 55 | 38 | 47 |
| Foundations | ..... | ..... | 5 |
| Generators | 15 | 12 | 14 |
| Switchboards | ..... | ..... | 3 |
| Total | 171 | 107 | 140 |

If the costs for gas engines given in Par. **526** are used, these totals will be from $10 to $20 higher.

Digitized by Google

### TESTING

**546. The essential measurements for determining producer efficiency and capacity are**:—(a) weight of coal per hr.; (b) proximate analysis, B.t.u. per lb. and moisture in coal; (c) cu. ft. of gas made; (d) temperature of gas, humidity; (e) calorific value and analysis. Additional data required for full information include: (f) weight of dry ash per hr.; (g) proximate analysis and B.t.u.; (h) wt. of steam per hr.; (j) wt. of vaporizer and scrubber water per hr., and temperatures; (k) h.p. required for blowers or exhausters and tar extractors or washers; (l) grains of dust per cu. ft. in gas.

For most purposes, only the efficiency of the producer itself is desired. For full details of tests, see Gas Power Committee reports, A. S. M. E.

**547. The testing of gas engines** is very similar to that of steam engines. The essential data are: (a) i.h.p.; (b) b.h.p. or kw. output and generator efficiency; (c) r.p.m.; (d) explosions per min., if hit-or-miss governed; (e) cu. ft. of gas per min.; (f) calorific power of gas per cu. ft. Desirable additional data include: (g) jacket water per hr.; (h) inlet and outlet jacket water temperatures; (i) gas, air and exhaust temperatures; (k) amount of lubricant. All physical dimensions of the engine should of course be taken.

**548. The essential data for a plant test** consist of kw.-hr. output at switchboard and coal used in producers; or cu. ft. of gas and calorific power, if coke oven, blast-furnace, natural, or illuminating gas is used.

**549. For gas measurement** the gas meter is chiefly used; the method of measuring the fall of a gas holder for volume should never be employed as the change of temperature ordinarily possible, entirely vitiates the accuracy. The Venturi meter furnishes an accurate and inexpensive measuring device if properly handled and kept clean in the throat.

**550. Indicated h.p.** is obtained by the usual indicator, but equipped with 0.5 in. area piston for this work.

**551. The calorific value of gas** can be obtained by the Junkers or other make of gas calorimeter. **Grains of dust per cu. ft.** are obtained by a special filter apparatus and test gas meter; the dust of a measured quantity of gas is collected and weighed. **Other measurements** are similar to those for steam engines (Par. 427).

**552. The duration of test** should be about the same as for engine and boiler tests generally. For Venturi readings, a record is best, or very frequent readings, say once a minute. The producer test should preferably not be less than 24 hr. except with small producers intended for intermittent use; the longer the test the better.

**553. For full calculation of results** the heat balance is required. The reports of the gas power committee, A. S. M. E., furnish full data for the elaborate tests.

## OIL POWER PLANTS

### BY REGINALD J. S. PIGOTT

### OIL ENGINES

**554. The thermodynamics of the explosion cycle (Otto) type** of oil engine are exactly the same as for gas engines (Par. 496 to 508). **The constant-pressure cycle** (Brayton cycle), of which the **Diesel** is the principal example, has slightly different events. For the **four-cycle type**, the inspiration and compression strokes are the same, but are made upon air only; at the end of compression, the oil fuel is injected, and burned, in such a way as to maintain a practically constant pressure during the early part of the working stroke. Expansion and exhaust then follow as in the gas engine.

**555. Thermodynamic equations.** For the air card, or ideal cycle, $p_b$, $t_b$, and $v_b$ are obtained as for the Otto cycle. Par 497 to 501., when burning fuel at constant pressure:

$$p_c = p_b \qquad (87) \qquad p_d = \left(p_c \frac{v_c}{v_d}\right)^{1.4^1} \qquad (91)$$

Digitized by Google

$$t_c = t_b\left(1+\frac{Q_1}{c_p\, t_b}\right) \quad (88) \qquad t_d = t_a\frac{p_d}{p_a} \quad (92)$$

$$v_c = v_b\frac{t_c}{t_b} \quad (89) \qquad Q_2 = C_v(t_d - t_a) \quad (93)$$

$$v_d = v_a \quad (90) \qquad E = \frac{Q_1 - Q_2}{Q_1} \quad (94)$$

where $p_a$, $p_b$, $p_c$, $p_d$ = inspiration, compression, combustion and release pressures, respectively, in lb. per sq. ft.; $v_a$, $v_b$, $v_c$, $v_d$ = volumes in cu. ft. at beginning of compression, end of compression, end of combustion or beginning of expansion, respectively; $t_a$, $t_b$, $t_c$, $t_d$ = absolute temperatures, at the same points in deg. Fahr.; $Q_1$ = heat added per lb. of gases, in B.t.u.; $Q_2$ = heat abstracted per lb. of gases in exhaust, in B.t.u.; $E$ = thermal efficiency; $C_v$ = specific heat at constant pressure.

**556. The thermal efficiency** would be the same as for the Otto cycle, if complete expansion occurred for the same compression pressures. But as expansion is always incomplete, the efficiency is less; this is more than offset by the much higher compression possible with the Diesel cycle.

**557. Types.** The types are the same as for gas engines; see Par. **502** and **503**.

**558. Mean effective pressure** of the Diesel type is given by

$$\text{M.e.p.} = J\frac{[Q_1 - C_v t_a(Y^{1.41}-1)]}{144\, v_a\left[1-\frac{p_a^{0.71}}{p_b}\right]} \quad (95)$$

$$Y = 1+\frac{Q}{C_p t_a} \quad (96)$$

where $J$ = Joule's equivalent, 777.5; $C_v$ and $C_p$ = specific heat at constant volume and constant pressure, respectively; $t_a$, $v_a$, $p_a$, $p_b$ are the same as in Par. **554**.

Lucke gives the following usual m.e.p.

| Kerosene | | Gasolene | |
|---|---|---|---|
| Absolute compression pressure | Observed m.e.p. | Absolute compression pressure | Observed m.e.p. |
| 46 | 40 | 66 | 106 |
| 63 | 69 | 70 | 75 |
| 65 | 68 | 75 | 100 |
| 68 | 40 | 86 | 70 |
| 70 | 72 | 86 | 72 |
| 50 | 35 | 95 | 60 |
| 55 | 85 | .. | .. |

**559. Speed and power.** The speed is the same as for gas engines of the same power (Par. **511**). For indicated and b.h.p. see Par. **512**.

**560. Kerosene engines** of the Miets and Weiss and Hornsby-Akroyd types are built in sizes up to 250 h.p. and operate in the same general manner as gas engines, the fuel being pumped in and vaporized in a hot tube, hot bulb, or vaporizing chamber. The hot tube and the hot bulb are kept warm by being left unjacketed, and by the combustion of a portion of the charge in the hot bulb chamber. Compression forces up the temperature of the charge enough for ignition to take place. Kerosene engines are the least efficient of the oil engines.

**561. Gasolene engines** are practically unused for power-station purposes, on account of expensive fuel, and low relative economy.

**562. The crude oil engine** is arranged like the kerosene engine, except that more careful arrangements must be made for preheating the oil for vaporization, and in most cases, the air also. Exhaust gas jackets are generally used for the purpose of providing the necessary heat.

Digitized by Google

**563. The Diesel engine** is now the most important of the oil engines on account of its remarkable efficiencies. It is built in both two-cycle and four-cycle types, and practically always vertical, single acting. It requires separate compressed-air starting sets, at about 1,000 lb. per sq. in. pressure. In the two-cycle type, separate air pumps (cylinders driven from the crosshead) are employed, as well as the fuel pump, which is always necessary.

**564. Weights.** The Diesel and the Junkers engines are the heaviest of prime movers, running from 400 to 600 lb. per b.h.p. The enormous weight is due chiefly to the heavy pressures, 500 lb. per sq. in. being an ordinary compression, with safe design allowance up to 1,000 lb. per sq. in. to safeguard against breakage due to preignition.

**565. The capacity of oil engines** is based on cu. ft. of cylinder displacement, as for gas engines (Par. **515**).

**566. Builders' rating.** Ulbricht and Torrance (*Power*, 1912) give average practice in builders' rating (for oils and distillates), as

$$\text{b.h.p.} = \frac{d^2\, ln}{21{,}875} - 0.75 \qquad (97)$$

where $d$ = cylinder diameter, in in; $l$ = stroke in in. $n$ = r.p.m. The rating is about 10 to 20 per cent. less than the ultimate capacity.

**567. The fuel consumption** is poorest for the gasolene and kerosene engines, running from 13,000 to 15,600 B.t.u. per b.h.p.-hr.; 9,400 to 10,000 B.t.u. per b.h.p. hr., for American Diesel engines. The German Diesel and Junkers engines run as low as 7,100 to 8,500 B.t.u. per b.h.p.-hr. All figures are for full load. These figures correspond to 0.65 to 0.78 lb. of gasolene or kerosene per b.h.p.-hr.; 0.48 to 0.52 lb. of oil for American Diesels; 0.37 to 0.44 for German Diesel and Junkers Engines. Fuel consumption decreases with size.

**568. Test of Falk kerosene oil engine** (H. D. Wile, Elec. World, 1913)

**570. The efficiency of gasolene engines** at full load varies from 18 per cent. at 10 b.h.p. per cylinder, to 20 per cent. at 22 to 32 b.h.p. per cylinder; **kerosene engines**, 1 to 2 per cent. less; **American Diesel engines**, from 26 per cent. at 60 b.h.p. per cylinder end, to 27 per cent. at 100 b.h.p. and over, per cylinder end; **German Diesels**, from 33 per cent. at 60 b.h.p. per cylinder end, to 36 per cent. at 100 h.p. All figures are at full-load.

**571. The overload capacity** of oil engines is not more than 10 to 20 per cent. above the rated capacity.

**572. Governing** in oil engines is chiefly by throttling the oil supply to the cylinder. The Miets and Weiss kerosene engine governs by the hit-or-miss principle on the oil pump.

**573. Ignition** in some of the kerosene engines, and all of the gasolene engines, is by electric spark, usually make-and-break. Some of the kerosene engines operate with hot bulb. The Diesel types and most of the heavy oil types ignite by means of the heat due to high compression.

**574. The operation** of the kerosene and other low-compression oil engines is practically the same as for gas engines. The hot-tube systems require occasional removal for cleaning of carbon deposit, and clearing the oil holes. The Diesel engine, however, requires the highest class of operating labor, on account of the high pressures employed, and the lubrication difficulties. These objections are reflected in the lower efficiency of American engines compared with English or German types, because the compression pressures have been reduced to relieve pressure and lubrication troubles, and thus obviate the use of such highly skilled labor.

**575. The cost of internal combustion engines** is given by A. A. Potter (*Power*, 1913) as follows: Gasolene, up to 100 h.p., hit-and-miss governed,

**569. Summary of Tests of 225-h.p. Diesel Engine**

| | Number of test | | | | | |
|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 |

Digitized by Google

Total cost = 141 + 24.8 (b.h.p.) (dollars) (98)

Gasolene, up to 75 h.p., throttle governed,

Total cost = 309 + 36.1 (b.h.p.) (dollars) (99)

Oil engines, up to 400 h.p.,

Total cost = 63.8 (b.h.p.) − 316 (dollars) (100)

Diesel engines, from 100 to 1,000 h.p., approximately (price varies very widely),

Total cost = 58.0 (b.h.p.) + 2,000 (dollars) (101)

Stott, Pigott, and Gorsuch, A.I.E.E. *Proceedings*, June, 1914, give 95.00 per kw. for all sizes of Diesel engines. This is due to the fact that weight per kw. *increases* with size.

**576. Test of a low-compression heavy oil engine.** (A. A. Potter and W. W. Carlson, *Elec. World*, 1913)

Digitized by Google

### PLANT DESIGN

**578. General.** What has been given in Par. 394 to 414 can be applied in principle to the oil plant. But inasmuch as the only auxiliaries are the exciters, jacket pumps and air compressors for starting, the problem is much simpler, and the economy of the plant is much more nearly that of the main unit.

**579. Plant costs.** The buildings will cost from $10.00 to $24.00 per kw., as no producer room or boiler room is required. The oil storage tanks require approximately 0.06 to 0.08 gal. capacity per kw. and cost from $3.00 to $6.00 per kw. of rated capacity. All other auxiliaries, including crane, oil pumps, air compressor and compressed air tanks, cost from $2.50 to $5.00 per kw. of rated capacity, installed. The total costs will range as follows, per kw.:

| | High | Low |
|---|---|---|
| Diesel engine | $100.00 | $95.00 |
| Building | 24.00 | 10.00 |
| Tanks | 6.00 | 3.00 |
| Auxiliaries | 5.00 | 2.50 |
| Piping | 1.70 | 0.50 |
| Totals | 136.70 | 111.00 |

There are no plants in this country much larger than 1,500 kw. in total capacity.

### TESTING

**580. The testing of oil engines** is exactly similar to the testing of gas engines, except that weight of oil per hr. is substituted for cu. ft. of gas per min. All other data and instruments required are the same.

## POWER PLANT BUILDINGS AND FOUNDATIONS

### BY REGINALD J. S. PIGOTT

**581. The building housing** any kind of power plant should be entirely fireproof. In many cases, no fire insurance is carried, and therefore all wood and other unnecessary combustible should be kept out of the structure.

**582. The approved constructions are:** (a) Steel structure, brick walls, concrete, slate or tile roof. For small low-grade plants corrugated iron may be employed to a very limited extent. (b) Steel framework, walls and roof concrete. (c) Reinforced concrete throughout. Type (c) is exploited chiefly in the hydroelectric plants; type (a) is the most widely employed. Concrete **foundations,** for all work, are practically universal.

**583. The general arrangement of engine rooms** in the older plants and in the most modern, is parallel to the boiler room. About 8 years ago the sudden increase in capacity of the turbine without much increase in size made the use of cross firing aisles necessary, to get in enough boilers. But the underfeed stoker has so increased the forcing capacity of the boiler that this is now unnecessary.

**584. In gas-producer plants,** the producer room is generally arranged parallel to the engine room, although it may be entirely separate and some distance away, as in some recovery plants.

**585. The coal bunkers in larger power plants** are of steel framing with concrete arch lining. For moderate size plants, and for outdoor bunkers for producer plants, the suspended type, catenary-curve bunker is widely used; also steel with concrete lining. Hoppers and chutes for coal, are made of plate steel or cast iron; ash hoppers, of plate steel lined with red brick, or reinforced concrete.

Digitized by Google

**586. Brickwork for power-station buildings** varies about as given below.

| | |
|---|---|
| Heavy basement work, labor cost only | $7.00 to $9.00 per M. |
| 18 in. walls | 8.00 to 10.00 per M. |
| 13 in. walls | 9.00 to 11.00 per M. |
| 18 in. wall, faced on one side with pressed brick | 12.00 to 14.00 |
| 18 in. wall, faced on both sides with pressed brick | 16.50 to 19.00 |
| 13 in. wall, faced on one side with pressed brick | 14.00 to 17.00 |

This is for straight wall work. For work much cut up by windows and corners, these prices must be increased. Common red brick costs about $8.00 per M delivered in or near cities.

**587. Concrete.** Taylor and Thompson give the following approximate cost for concrete:

| Item | Per cubic yard | |
|---|---|---|
| | Range | Average |
| Mass foundations | $4.00 to 6.00 | $7.00 |
| Conduits and sewers | 5.00 to 16.00 | 9.50 |
| Tunnels, subways | 6.00 to 42.00 | 15.00 |
| Reinforced retaining walls | 12.00 to 15.00 | 13.50 |
| Reservoirs, filters | 6.00 to 23.00 | 10.50 |
| Tanks, standpipes | 4.00 to 20.00 | 12.00 |
| Buildings, total structures | 8.00 to 26.00 | 14.00 |
| Walls in building construction | 12.00 to 25.00 | 17.50 |
| Encasing structural steel in concrete | 14.00 to 21.00 | 18.50 |
| | Per linear ft. | |
| Concrete piles | 0.51 to 1.60 | 1.15 |

**588. Structural steel for building purposes** costs from $55 to $120 per ton, erected. For any amount over 200 tons, it should not ordinarily exceed $65 per ton.

**589. Building foundations** are made almost exclusively of mass concrete (Par. 587).

**590. The bearing power of soils** for computing the proper spread of footings is given below.

| Soil | Tons per sq. ft. | Remarks |
|---|---|---|
| Good solid natural earth | 4.0 | New York Building Laws |
| Pure clay, 15 ft. with no admixture of foreign substances except gravel. | 1.75 | Chicago Building Ordinances |
| Dry sand, 15 ft. thick, no admixture of foreign substances. | 2.0 | Chicago Building Ordinances |
| Clay and sand mixed | 1.5 | Chicago Building Ordinances |
| Hard rock on native bed | 2.50 | Richey |
| Ledge rock | 36.0 | Richey |
| Hard-pan | 8.0 | Richey |

**591. For making concrete in any quantity,** machine mixing always pays, both in first cost and in reliable quality. **Form work** is usually of 1.25-in. tongued and grooved, short-leaf yellow pine lumber dressed one side, with 2 in. x 4 in. rough spruce or yellow pine studs and bracing for the greater part; 4 in. x 4 in. studs, and larger, are used only where necessary.

### 592. Loads on Foundation

(Chicago Building Ordinances)

| Foundation | Tons per sq. ft. | Foundation | Tons per sq. ft. |
|---|---|---|---|
| Concrete | 4.0 | Iron rails in concrete | 6.0 |
| Foundation piers, dimension stone. | 5.0 | Steel rails in concrete | 8.0 |
| Brick piers in cement | 9–12.5 | Piles | 12.0 |

**593. Machinery foundations** are generally of mass concrete, as for buildings. But lately the demands for condenser and auxiliary space under steam turbines have forced the use of **structural steel foundations.** There is no objection objection to this, provided the turbine is properly balanced and the maximum permissible deflection of about 0.02 in. is not exceeded. Foundations should extend up to 1 in. or ¼ in. below the bottom line of the machine base to be set; and when the latter is lined up, the whole should be grouted with cement grout, mixed 1 : 2, of cement and sand. **Foundation bolts** are now seldom set from templates, but are accurately located in the forms by drawing dimensions. Each bolt is mounted in a pipe sleeve large enough to allow a play of at least one diameter for taking care of inaccuracies in the casting and in the setting. With some turbines, no bolts whatever are needed.

**594. Drainage** should if possible be arranged for by placing the whole station above sewer or tide-water level, so that gravity flow from sumps and traps is possible. Where this cannot be done, suitable reservoir sumps must be provided, emptied by ejectors or pumps, float controlled. Galvanized iron or cast-iron roof leaders may be employed, with cast-iron soil pipe in the ground, or glazed clay tile pipe.

**595. Lighting and ventilation.** The use of all-glass monitors is the most desirable way of lighting and ventilating plants. The rolled steel section windows and monitors now produced have rendered easy the problem of fireproof, permanent window and ventilator fixtures. The operating devices should be arranged for quick opening and closure, to provide for storm protection. The continuous sash for monitor use is the latest device in this line. Care should be taken to make windows rain- and snowproof, and to allow opening for ventilation without letting in rain during ordinary storms.

**596. Lighting by daylight** is accomplished by the monitors above mentioned and by high side windows in some cases. The night illumination in most cases is by incandescent lamp. The arc and Nernst lamps are generally undersirable; the mercury vapor lamp is very successful where used, and is the least injurious to eyesight, but there is much general objection to the color of the light. The usual demand for illumination in a power station will take from 0.2 to 0.5 per cent. of the output.

**597. Fire risks** in well constructed plants are exceedingly low; in many of the largest plants, no insurance against fire is carried. The use of wood roofs or other inflammable structures, makes insurance imperative.

**598. The cost of buildings** for various types of power plant is given in Par. **413, 545** and **579** per kw. of capacity. The cost per cu. ft. of contents is less variable, and runs from $0.20 to $0.35.

## HYDRAULIC POWER PLANTS

**BY ARTHUR T. SAFFORD**

*Consulting Hydraulic Engineer, Member, American Society of Civil Engineers, Member, American Society of Mechanical Engineers*

### HYDRAULICS

**599. Pressure and depth.** Water is but slightly compressible, therefore the pressure, $P$, is for all practical purposes directly proportional to the depth, $H$, and can be represented by a diagram as shown in Figs. 46 to 49.

Digitized by Google

**The total pressure on any submerged surface** is equal to the area of the pressure diagram (*abc*, Fig. 46; *decb*, Figs. 47 and 48) and the centre of pressure passes through its centre of gravity, *G*, perpendicular to the submerged surface. The moment of the pressure about *c* is (Fig. 49),

$$M = Py \qquad \text{(ft-lb.)} \qquad (102)$$

The pressure in lb. per sq. in. at any point is

$$p = 0.433 \times \text{Depth} \qquad (103)$$

The pressure is always normal to the submerged surface. The total pressure exerted on a submerged body is

$$P = 62.4HA \qquad \text{(lb.)} \qquad (104)$$

wherein *H* is the depth of water in feet over the geometrical centre of the body and *A* is the area of the surface in sq. ft.

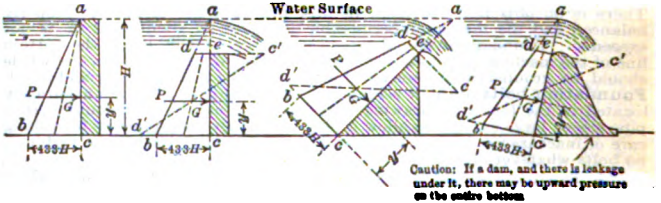

FIG. 46. FIG. 47. FIG. 48. FIG. 49.

**600. Possible upward pressure under dams.** If the structure is a dam and there is leakage under it there may be upward pressure over the entire bottom. If there is no leakage then there will be no upward pressure. The truth in any given case probably lies between these two extremes and the foundations and underlying material must be carefully studied to make a proper design.

**601. The dynamic properties of water in motion** are theoretically the same as those of falling bodies *i.e.*:

$$V = \sqrt{2gh} = 8.02\sqrt{h} \qquad \text{(ft. per sec.)} \qquad (105)$$

where $g = 32.16$.

Actually this formula is rarely exact and expressions based upon it must be modified by empirical coefficients.

**602. The quantity of water passing a given point in a unit of time** is equal to the product of the net cross-sectional area taken perpendicular to the line of flow and the mean velocity in that time parallel to the line of flow. This may be expressed by the equation

$$Q = AV \qquad \text{(sec-ft.)} \qquad (106)$$

If *A* is the area in square feet, *V* the velocity in feet per second, then *Q* is the quantity in cu. ft. per sec., or, in its briefer form, second-feet. This in the United States is now the common expression in water-power practice for flow of streams, capacity of canals and raceways and discharge of waterwheels.

**603. At every section of a continuous and steady stream the total energy is constant**; whatever head is lost as pressure is gained as velocity. This is known as **Bernoulli's theorem**, and in terms of head can be expressed as follows: Total head = velocity head + pressure head + head due to elevation = constant; or in every stream section,

$$H_T = h_v + h_p + h_e = \frac{V^2}{2g} + \frac{p}{y} + h_e \qquad \text{(ft.)} \qquad (107)$$

where *y* is the constant to reduce lb. per square inch to head in feet, or 0.433.

In order to make this equation of practical application, a term representing the head lost in overcoming friction, $h_\lambda$, must be added on the right-hand side of the equation. This formula, properly modified to include the effect of

Digitized by Google

frictional resistances, is the basis of all empirical formulas for the flow of water.

**604. Power and energy.** The potential energy of water held in reserve is its weight multiplied by the net available distance through which it can fall in the performance of work. As power expresses the rate of doing the work, it is convenient to deal with the flow of water in cu. ft. per sec. falling through a given vertical distance in feet. Power = $62.4QH$ ft-lb. per sec., where $Q$ is the flow in cu. ft. per sec., and $H$ the vertical distance or "head" in feet and 62.4 is the weight in pounds of 1 cu. ft. of water.

$$\text{Horse-power} = \frac{62.4QH}{550} = \frac{QH}{8.8} \qquad (108)$$

This is the maximum horse-power that might be obtained from $Q$ cubic feet of water per second falling a distance $H$ feet, assuming an efficiency of transformation of energy of 100 per cent. This expression multiplied by the known efficiency of a water wheel will give the power at the water-wheel shaft. Ordinarily $QH/11$ or $QH/12$ will give approximately the net water horse-power, corresponding respectively to efficiencies of 80 per cent. and 73.3 per cent.

## FLOW FORMULAS

**605. Orifices employed as meters,** are limited in use; experimentally they have given very consistent results, but in practice these results often cannot be reproduced with sufficient accuracy for precise work. Orifices of relatively small sizes, of regular shapes (usually round or rectangular), with carefully made edges, and used with full contraction of the jet, have been carefully experimented upon and may be used with confidence provided there is practically no velocity of approach (less than 0.5 ft. per sec.).

**606. The flow of water through an orifice** (Fig. 50) in a vertical wall expressed in cubic ft. per sec. is

$$Q = CAV = CA\sqrt{2gh} \quad \text{(cu. ft. per sec.)} \qquad (109)$$

where $A$ is the area of the opening in square feet, $h$ the head in feet measured from the surface of the water to the center of the opening, and $C$ is the coefficient of discharge which depends on the form of the orifice. For sharp-edged orifices, 4 sq. ft. or less in area, with full contraction of the issuing stream (Fig. 50), discharging under heads from about 1 to 20 times the depth of the orifice (practically no velocity of approach), a value of $C$ may be taken as 0.6. If the orifice is large and the head acting is small, the exact or integral form of the equation* must be used when $C$ is taken as 0.6. For high heads and relatively small orifices this is not necessary. If the contraction is even partly suppressed the results are unreliable; if wholly suppressed the orifice becomes a short tube or nozzle and the coefficient varies greatly, depending on the shape and proportions; but always more than 0.6 (see Par. **635**).

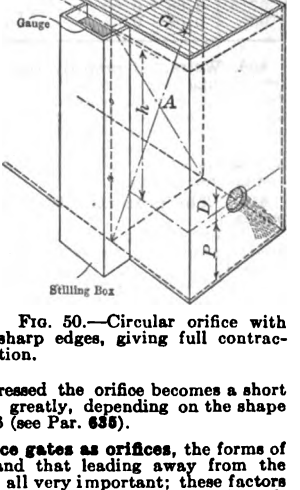

FIG. 50.—Circular orifice with sharp edges, giving full contraction.

**607. In treating head gates and sluice gates as orifices,** the forms of cross-section, the channel of approach and that leading away from the orifice, and the velocity of approach are all very important; these factors modify any computed discharge based upon the opening and observed head.

* Water Supply and Irrigation Paper No. 200.

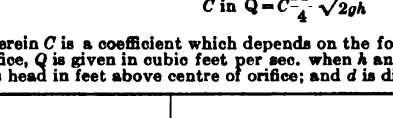
Digitized by Google

The coefficient of discharge for gates on the basis of their cross-sectional area and the head measured above and below them may vary all the way from that of a standard sharp-edged orifice (0.6) to over 1.0 if there is much velocity of approach. For these reasons, if head gates or sluice gates are to be used as measuring devices they should be given their own rating by some independent method of measurement.

### 608. Weisbach's Coefficients

$$C \text{ in } Q = C\frac{\pi d^2}{4}\sqrt{2gh} \qquad (109A)$$

wherein $C$ is a coefficient which depends on the form and head $h$ acting on orifice, $Q$ is given in cubic feet per sec. when $h$ and $d$ are measured in feet; $h$ is head in feet above centre of orifice; and $d$ is diameter of orifice in feet.



| S. deg. | $C$ | $C$ | Inlet slightly round $C=0.90$ | Depending upon smoothness surface $C=0.96$ to 0.99 | Depending on the length and velocity $C=0.96$ to 1.5 | $d$ | $h=1.148$ $C$ | $h=1.969$ $C$ |
|---|---|---|---|---|---|---|---|---|
| 0. | 0.97 | 0.54 | | | | 0.0144 | 0.68 | 0.66 |
| 5.75 | 0.95 | ..... | | | | 0.0328 | 0.64 | 0.63 |
| 11.25 | 0.92 | ..... | Inlet very round $C=0.97$ | | | 0.0656 | 0.63 | 0.62 |
| 22.5 | 0.90 | 0.55 | | | | 0.0984 | 0.62 | 0.61 |
| 45. | 0.75 | 0.58 | | | | 0.1312 | 0.614 | 0.607 |
| 67.5 | 0.68 | 0.60 | | | | | | |
| 90. | 0.63 | 0.63 | | | | | | |

**609. Weirs,*** if properly constructed and used with faithful regard to reproducing the exact conditions which obtained when the experimenter derived his formula, should give good results. Some extraordinary results have been obtained because these precautions were not observed; and weir measurements unless standardized will gradually lose their hold. A weir installation in a power plant must necessarily cut down the available head by roughly 3 ft. For this reason the weir should be used only for testing, and not for operating.

**610. "The procedure to be followed in weir measurements comprises:†**

(*a*) Constructing and setting up the weir and the gage for measuring the head; reproducing, if possible, the experimental conditions of the formula to be used.

(*b*) Measuring the length of the crest and determining its irregularities if any.

(*c*) Taking a profile of the crest if not sharp-edged.

(*d*) Determining by actual measurements the cross-sectional area of the channel of approach.

(*e*) Establishing by leveling the relative elevations of the crest of the weir, and the zero of the gage.

(*f*) When the desired regulation of flow is established, determining the head by hook gage or other observations at intervals as frequent as the conditions require.

---

* For the most extended compilation and examination of existing weir data Water Supply and Irrigation Paper No. 200 (Weir Experiments, Coefficients, etc., by R. E. Horton) should be consulted.

† Hughes and Safford, "Hydraulics;" New York, MacMillan Co., 1911; page 196.

Digitized by Google

(*g*) If possible, measure the actual velocity in the channel of approach by a current meter or some other direct method; and

(*h*) Compute the discharge by the formula selected. Three of these operations require especial consideration, viz.: construction and setting, the measurement of the head, and the selection of the formula."

FIG. 51.—Weir with end contractions.

FIG. 52.—Weir with end contractions suppressed.

**611. "Construction and setting of weirs."** In order to eliminate as far as possible factors for which precise allowance cannot be made, the construction and setting should meet the following conditions:

(*a*) A sharp-crested weir with complete crest contraction should be used.

(*b*) The crest should be level, and its ends vertical.

**612. Standard Weir Formulas (Par. 613 to 621)**

| Experimenter | Formula (cu. ft. per sec.) | Limits of head recommended (ft.) | Distance of crest above bottom (ft.) | Correction for end contraction | Correction for velocity of approach | |
|---|---|---|---|---|---|---|
| | | | | | Suppressed weir | Contracted weir |
| Fteley & Stearns | $Q = 3.31L\sqrt{H^3} + 0.007L$ | 0.07 to 0.50 | At least 2.0 | $L = (L - \frac{NH}{10})$ * | $H = (h + 1.50h_v)$ | $H = (h + 2.05h_v)$ |
| Francis | $Q = 3.33L\sqrt{H^3}$ | 0.50 to 2.00 | At least 3 times the observed head | $L = (L - \frac{NH}{10})$ | $\sqrt{H^3} = (h - h_v)^3 - h_v^3$ | ..... |
| Hamilton Smith | $Q = (C_s \text{ or } C_c)\frac{2}{3}L\sqrt{2g}H^{\frac{3}{2}}$ | 0.10 to 1.70 | At least 3 times the observed head | Use proper coefficient | $H = (h + 1 - \frac{1}{2}h_v)$ | $H = (h + 1.4h_v)h_v$ |
| Bazin** | $Q = mLh\sqrt{2gh}$ | 0.20 to 2.00 | ..... | ..... | ..... | ..... |

* Fteley & Stearns [illegible] $H$

* Hughes and Safford, "Hydraulics;" New York, MacMillan Co., 1911.

Digitized by Google

(*c*) The end contractions should be complete, or, if suppressed, entirely suppressed.
(*d*) The upstream face should be vertical; the downstream face so designed that the nappe has free overfall.
(*e*) Free access for air under the nappe should be made certain.
(*f*) The weir should be set at right angles to the direction of flow.
(*g*) The channel of approach should be straight for at least 25 ft. above the weir, of practically uniform cross-section and of slight slope (preferably none).
(*h*) Screens of coarse wire or baffles of wood should be set in the channel, if necessary, to equalise the velocities in different parts of the channel, but not nearer the crest than 25 ft.
(*i*) The channel of approach should have a large cross-sectional area in order to keep the velocity of approach low."

A weir with complete end contractions is shown in Fig. 51; suppressed end contractions are shown in Fig. 52.

**613. Francis formulas.** The best known formulas are those of James B. Francis and M. Basin. The Francis formulas are strictly applicable only to **vertical, sharp-crested weirs** with free overfall and either with no end contractions ("suppressed weir"), or with complete end contractions and: (*a*) when the length of the weir is at least 5 ft.; (*b*) when the head ($H$) is not greater than one-third the length ($L$); (*c*) when the head is not less than 0.5 ft. nor more than 2 ft.; (*d*) when the velocity of approach is 1 ft. per second or less; (*e*) when the height of the weir crest above the bottom of the channel of approach is at least three times the head. For tabulation of standard formulas see Par. **612**.

**614. Smith's formulas.** For **short weirs** (shorter than 5 ft.) the experiments and studies made by Hamilton Smith, Jr., afford the best guide (See Smith's weir coefficients, Par. **620**).

**615. Basin's formula.** The best weir experiments abroad are those of M. Basin whose general formula is $Q = mLh\sqrt{2gh}$ for suppressed weirs only. At about 1.0 ft. depth on the crest, with no velocity of approach, the results from his standard 8.56-ft. (2-meter) weir are practically those of James B. Francis' standard 10-ft. weir (See Par. **621**).

**616. Fteley and Stearns' formula.** For heads from 0.07 to 0.5 ft. the Fteley and Stearns formula* $Q = 3.31L\sqrt{H^3} + 0.007L$ is recommended.

**617. Weir discharge tables.** The following table of discharges for weirs without end contractions, and velocity head is given for heads from 0.00 to 2.98 ft. and includes figures from the Fteley and Stearns formula up to 0.5 ft. and the Francis formula from 0.5 ft. to 2.98 ft. The quantity of water is given in cu. ft. per sec., per foot of weir, with complete contraction on the crest, and no end contractions. $Q = 3.31L\sqrt{H^3} + 0.007L$ for depths up to 0.5 ft. and $Q = 3.33L\sqrt{H^3}$ for depths above 0.5 ft.; the velocity due to the head is computed by formula, Vel. $= \sqrt{2gh}$.

---

* Fteley and Stearns, in "Sudbury River Experiments" (page 84) state that this formula is based upon experiments in which the depths on the weir ranged from 0.07 to 1.63 ft. *Trans.* Amer. Soc. Civil Eng., Vol. XII.

**618. Examples of weir calculations.** A weir 5 ft. long is set in a channel 10 ft. wide and the crest is 4.36 ft. high. If the observed head is

Digitized by Google

0.64 ft., compute the discharge (*a*) by the Francis, (*b*) by the Fteley and Stearns, (*c*) by the Smith formula.

(*a*) Francis formula: $Q = 3.33\ (5 - 0.1 \times 2 \times 0.64)\ \sqrt{0.64^3} = 3.33 \times 4.872 \times 0.512 = 8.31$ cu. ft. per sec.; not corrected for velocity of approach $V_A$ Area of channel of approach $A = (4.36 + 0.64)\ 10 = 50$ sq. ft. Velocity of approach $V_A = Q/A = 8.31/50 = 0.1662$ ft. per sec. Velocity head $h_v = (0.1662)^2/64.32 = 0.0004$; $\sqrt{H^3} = \sqrt{(0.64 + 0.0004)^3} - \sqrt{0.0004^3} = 0.5125 - 0.000008 = 0.5124$; $Q = 3.33 \times 4.872 \times 0.5124 = 8.313$ cu. ft. per sec.

(*b*) Fteley and Stearns formula: $Q = 3.31\ (5 - 0.1 \times 2 \times 0.64)\ \sqrt{0.64^3} + 0.007 \times 5 = 3.31 \times 4.872 \times 0.512 + 0.007 \times 5 = 8.29$ cu. ft. per sec.; $h_v$ (as above) $= 0.0004$; $H = 0.64 + 2.05 \times 0.0004 = 0.6408$; $\sqrt{H^3} = 0.513$; $Q = 3.31 \times 4.872 \times 0.513 + 0.007 \times 5 = 8.31$ cu. ft. per sec.

(*c*) Hamilton Smith formula: $Q = 0.607 \times \frac{2}{3} \times 5 \times 8.02 \times \sqrt{0.64^3} = 8.308$ cu. ft. per sec.; $h_v$ (as above) $= 0.004$; $H = 0.64 + 1.4 \times 0.0004 = 0.6406$; $\sqrt{H^3} = 0.5127$; $Q = 0.607 \times \frac{2}{3} \times 5 \times 8.02 \times 0.5127 = 8.320$ cu. ft. per sec.

In the foregoing solutions it is seen that the effect of velocity of approach is negligible, as is usually the case when the velocity is less than half a foot per second.

**619. Further examples of weir calculations.** Given a suppressed weir 7 ft. long, with crest 4.5 ft. above the bottom of the channel; the observed head is 1.36 ft. Compute the discharge by the Francis, Fteley and Stearns, and Basin formulas: (*a*) not correcting for the velocity of approach; (*b*) correcting for the velocity of approach.

(*a*) Francis formula: $Q = 3.33 \times 7 \times \sqrt{1.36^3} = 36.97$ cu. ft. per sec. Fteley and Stearns formula: $Q = 3.31 \times 7 \times \sqrt{1.36^3} + 0.007 \times 7 = 36.80$ cu. ft. per sec.

(*b*) Francis formula: $A = 7 \times 5.86 = 41.02$ sq. ft.; $V_A = Q/A = 36.97/41.02 = 0.90$ ft. per sec.; $h_v = (0.90)^2/64.32 = 0.0126$ ft.; $\sqrt{H^3} = \sqrt{(1.36 + 0.0126)^3} - \sqrt{0.0126^3} = 1.610$; $Q = 3.33 \times 7 \times 1.61 = 37.50$ cu. ft. per sec.

Fteley and Stearns formula: $V_A = 36.70/41.02 = 0.894$; $h_v = (0.894)^2/64.32 = 0.0124$; $H = 1.36 + 1.50 \times 0.0124 = 1.379$; $\sqrt{H^3} = 1.620$; $Q = 3.31 \times 7 \times 1.620 + 0.007 \times 7 = 37.58$ cu. ft. per sec.

Basin formula: Basin's coefficient (Par. **621**) includes effect of velocity of approach; $Q = 0.4266 \times 7 \times 1.36\ \sqrt{64.32 \times 1.36} = 37.97$ cu. ft. per sec.

**620. Smith's weir coefficients.** $C_s$ = coefficient for weirs with the contraction suppressed at both ends and complete crest contraction.

**622. Other forms of weir notches** have been proposed and used, the most common of which are of Cippoletti, a trapezoidal notch, and the **triangular notch** (Fig. 53). The object of the Cippoletti weirs was to eliminate the effect of the end contractions. According to experiments by Horton*

* Water Supply and Irrigation Paper No. 200 U. S. Geol. Survey; Washington, D. C.

Digitized by Google

when the batter of the sides is 1 in 4 this aim is accomplished. The formula for any **trapezoidal weir** takes the usual form

$$Q = CL\sqrt{H^3} \qquad \text{(cu. ft. per sec.)} \qquad (110)$$

in which $C$ for the special form cited has been experimentally determined as 3.367. Correction for velocity of approach may be made as for the Francis weir. The advantage of this weir is that a constant length $L$ may be used for all heads so that for continuous measurements with varying heads it saves much labor. This form has been much used in irrigation projects in the Western United States. By adding 1 per cent. to the value of $Q$ found in the weir table in Par. **617** the discharge for this weir may be computed.

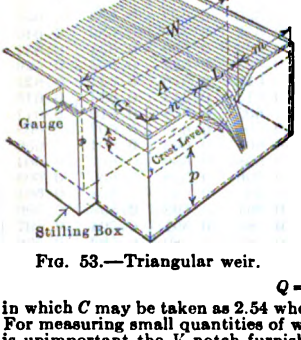

FIG. 53.—Triangular weir.

**623. Triangular (notch) weirs.** The common triangular notch is right angled, set with the apex down and the bisector of this angle vertical (Fig. 53). It has been found by experiment that the coefficient of such a triangular weir is remarkably constant for all heads. The formula for a right-angled notch set as described reduces to

$$Q = C\sqrt{H^5} \qquad \text{(cu. ft. per sec.)} \qquad (111)$$

in which $C$ may be taken as 2.54 when $H$ is measured to the apex of the angle. For measuring small quantities of water where the necessary head consumed is unimportant the $V$ notch furnishes an accurate means and has been developed commercially as the **Lea Recorder.**

**624. Flow of water in channels,** whether open or closed, is subject to the same fundamental laws, and the formulas in common use are based on the two primary conceptions stated in Par. **602** and **603.** Head is required to produce velocity, to overcome obstructions such as bends, sudden constrictions or enlargements and head is required to overcome friction. Friction in turn depends on the velocity of flow and on the surface over which the water flows, its extent, and its character. In any formula for discharge the extent of the rubbing surface in contact with the water may be cared for directly by a numerical factor known as the **mean hydraulic radius,** which is found by dividing the cross-sectional area of the stream by its wetted perimeter; the latter is the linear dimension of that part of the boundary line of the cross-section of a channel in contact with the water. The effect of the character of the surface must be cared for by empirical coefficients. Head may be provided by natural topographical conditions as in the slope of a river bed, or created artificially as in the case of an elevated reservoir feeding into a pipe line. In the formulas most commonly in use the head appears in the slope of the **hydraulic grade line** which is the fall in feet, per foot of distance, measured along the longitudinal axis. The hydraulic grade line is a line in the plane of the longitudinal axis of the stream and at all points distant from it an amount equal to the net effective head. In an open channel the hydraulic grade line is coincident with the surface of the water. In the case of a pipe or conduit flowing under pressure the hydraulic grade line is above the centre line of the pipe and distant from it as defined above.

**625. The Chezy formula** is probably the most satisfactory one to use, certainly for open channels. It is usually stated as follows:

$$V = C\sqrt{RS} \qquad \text{(ft. per sec.)} \qquad (112)$$

where $C$ = coefficient increasing with the mean hydraulic radius, and for new clean channels usually increasing with the mean velocity of flow, and decreasing with the roughness of the channel; $R$ = mean hydraulic radius, and $S$ = sine of the slope of the hydraulic grade line. The common text-book formula which, as nearly as may be determined, was proposed by Weisbach,*

* Weisbach's "Mechanics" (Coxe's translation), page 866. This formula is not uncommonly designated as Weisbach's, Darcy's, Weston's, or Chezy's.

Digitized by Google

and which is used only for pipes under pressure, is as follows (for steady uniform flow under pressure in circular pipes):

$$h_f = f\left(\frac{LV^2}{2gD}\right) \qquad \text{(ft.)} \qquad (113)$$

where $h_f$ = the head lost in friction, $f$ = the friction factor or coefficient of friction, decreasing with an increase in the diameter of the pipe and commonly with an increase of velocity of flow; and increasing with the age and roughness of the surface in contact with the water (Par. **626**). $L$ = the length (in ft.) of the pipe measured on its axis; $D$ = the internal diameter (in ft.) of the pipe; $V$ = the mean velocity of flow in ft. per sec.; $g$ = the acceleration due to gravity, taken here as 32.16. The above equations are merely different expressions for the same formula. Either may be used to suit convenience.

Values of $C$ suggested for use in Eq. 112 are as follows: New cast-iron pipe laid carefully without abrupt changes in grade or alignment: sizes 6 in. to 10 in., velocities 3 to 8 ft. per sec., $C = 102$ to 108; sizes 12 in. to 20 in., velocities 1 to 5 ft. per sec., $C = 105$ to 115; sizes 20 in. to 60 in., velocities 1 to 6 ft. per sec., $C = 120$ to 150. Riveted steel pipe (new): sizes 16 in. to 102 in., velocities 2 to 5 ft. per sec., $C = 100$ to 115. Tunnel or aqueduct with smooth cement or hard brick lining of relatively small cross-sectional areas (15 to 50 sq. ft.): velocities 1 to 5 ft. per sec., $C = 115$ to 140. Small canal, cross-sectional area about 100 sq. ft. in loose gravel or rock: velocities 3 to 5 ft. per sec., $C = 60$ to 85. Large canal, wide and shallow, smooth bottom and sides: velocities 2 to 5 ft. per sec., $C = 50$ to 70. Large canal, wide and deep, fairly smooth bottom and sides: velocities 2.5 to 3.5 ft. per sec., $C = 75$ to 90. Large river, tortuous channel: $C = 40$ to 80. Large river, easy bends: $C = 70$ to 100. Where the carrying capacity of any pipe or channel is very important about 30 per cent. depreciation should be figured in advance.

**626. Friction factors** ($f$ in Eq. 113, Par. **625**) for pipes may be computed by Weston's formula.* This formula, which must only be applied to pipes having interior sides similar to lead and brass pipes, from one-half inch to three and one-half inches in diameter is as follows:

$$f = 0.0126 + \frac{0.0315 - 0.06d}{\sqrt{v}} \qquad (114)$$

in which $d$ = internal diameter of the pipe in feet; and $v$ = the velocity in feet per second.

For pipes with interior sides similar to new cast-iron pipes the following formulas are used:

$$f = \left(0.017379 + \frac{0.0015965}{d} + \frac{0.0040723}{v} + \frac{0.000020816}{d^2}\right)\frac{l}{d}\frac{v^2}{2g} \qquad (115)$$

$$f = \left(0.0198920 + \frac{0.00166573}{d}\right)\frac{l}{d}\frac{v^2}{2g} \qquad (116)$$

The first formula (Eq. 115) is for velocities of flow less than 0.33 ft. per sec., the second for higher velocities.

**627. The Kutter formula** though intended and largely used for pipes as well as for open channels, is not recommended for general use in either case.

$$V = \left[\frac{41.66 + \frac{1.811}{n} + \frac{0.00281}{S}}{1 + \left(41.66 + \frac{0.00281}{S}\right)\frac{n}{\sqrt{R}}}\right] \times \sqrt{RS} \qquad (117)$$

To estimate directly a value of $C$ (Par. **625**) is simpler, and probably quite as accurate as to estimate a value of $n$. The value of $n$ depends on the value of $S$. Considering that in picking out the value of $n$ a variation of 0.001 for small values of $n$ and $R$ may change the value of $C$ as much as 17 per cent.,

* "Tables showing Loss of Head due to Friction of Water in Pipes" by Edmund B. Weston, C. E., D. Van Nostrand Co., 3rd Edition, 1903.

Digitized by Google

and for moderate values as much as 5 to 8 per cent., it should be obvious that hair-splitting calculations with the Kutter formula are a needless waste of time, producing merely numerical accuracy instead of a high degree of precision. Though it seems evident that we shall never have one formula to fit accurately all kinds of channels, it appears probable that we may have a small group of formulas each of which will fit some particular class of channels.

Values of $n$ to be used in the Kutter formula for calculating values of $C$ to be used in the Chesy formula are as follows:

$n = 0.01$: should never be used except for temporary work and then only for perfectly smooth, clean iron pipes under 8 in. diameter and for high velocities, or for temporary and new planed wooden stave pipes, at high velocity 10 in. and under in diameter.

$n = 0.011$: for above pipes, and low velocity.

$n = 0.012$: for above pipes 3 ft. or more in diameter and high velocities; old iron pipes 8 in. diameter or under, low velocities; old city water mains above 8 in. diameter. Also for concrete tunnels having $R = 2.5$; wood flumes, open, planed plank, long bends.

$n = 0.013$: for above pipes 36 in. to 120 in. diameter, old pipes and low velocities; 1-to-2 cement-lined pipes; new penstocks lined with unplaned lumber and running full at all times; large concrete-lined tunnels of area 100 to 200 sq. ft.

$n = 0.0135$: Ashlar masonry and well laid brickwork penstocks over 3 ft. in diameter; cast-iron concrete or steel-riveted pipes 8 in. to 20 in. diameter, long in use, short joints and under pressure of 75 to 150 lb. per sq. in.

$n = 0.015$: rough concrete pipes where the interior cannot be smoothed or kept clean, moderate velocities and diameters above 3 ft.; penstocks of poorly laid rough brickwork; concrete-lined, open canals, low velocities.

$n = 0.017$: canals with gravel bottom and sides well rammed, stones being 0.3 to 0.7 in. diameter; tunnels through hard rock, well trimmed and roughly faced; very large open concrete-lined canals.

$n = 0.02$: rough rubble masonry; canals through rock, or with bottoms and sides paved with cobble stones; canals in earth with bottoms and sides well trimmed; small rough lumber penstocks with battens and poor alignment.

$n = 0.0225$: canals in earth in good condition, but long in use, having moss growing freely.

$n = 0.025$: canals in clay, long in use; small rivers, deep and narrow and with no sharp bends, smooth sand bottoms and smooth uniform banks.

$n = 0.0275$: canals and rivers as for $n = 0.025$, but having an occasional bend and snag also the same, but with gravel bottoms; earth canals as left by dredging.

$n = 0.03$: rivers having loose boulder beds, irregular banks, sharp bends, shallow, normal flow.

$n = 0.035$: rivers with rough, irregular beds having shallows and pools, snags, bends, gravel bottoms, average flood stages.

$n = 0.05$: large shallow rivers, having sharp bends, low heavily wooded banks, snags, shallows, pools, rough bottom and moderate flood conditions.

$n = 0.055$: large torrential streams during high floods, with the banks heavily-wooded and inundated; mountain streams with many falls, large boulders, rapids, etc.

**628. Beardsley's formula for $C$.** Assuming values for $n$, $S$ and $R$, $C$ may be calculated from the formula as given by R. C. Beardsley.

$$C = \frac{\left(23 + \frac{1}{n} + \frac{0.00155}{S}\right)}{\left(0.5521 + \left[23 + \frac{0.00155}{S}\right]\frac{n}{\sqrt{R}}\right)} \tag{118}$$

or in its original form

$$C = \frac{\left(41.66 + \frac{1.811}{n} + \frac{0.00281}{S}\right)}{\left(1 + \left[41.66 + \frac{0.00281}{S}\right]\frac{n}{\sqrt{R}}\right)} \tag{119}$$

**629. Basin's formula for $C$.** Basin proposed a formula for computing the value of $C$ to be used in the Chesy formula which differs from the Kutter

Digitized by Google

formula in eliminating $S$ and making the variation in $C$ depend only upon variations in the mean hydraulic radius and the coefficient of roughness. It is as good as any general formula and has the advantage of simplicity. His formula is

$$C = \frac{157.6\ R^{\frac{1}{2}}}{R^{\frac{1}{2}} + \gamma} \qquad (120)$$

Values of $\gamma$

$\gamma = 0.109$: very smooth surfaces; neat cement; planed wood.
$\gamma = 0.290$: smooth surfaces; planks, bricks, ashlar.
$\gamma = 0.833$: rough surfaces; rubble masonry.
$\gamma = 1.54$ : canals with mixed linings; very regular earth or paved with stones.
$\gamma = 2.35$ : earth canals in ordinary conditions.
$\gamma = 3.17$ : earth canals in bad condition.

Bazin's formula represents the results of a very careful study of existing data and is extremely valuable in designing relatively small channels and those with very smooth linings; it also meets the conditions of design for all open channels as well as, if not better than any general formula available. It has the additional merit of simplicity.

**630. Friction loss in iron pipes increases with age.** Under ordinary conditions of service at the end of 30 years we may expect to find the losses in cast-iron pipes due to friction about doubled. This is satisfactory for rough approximations and the loss for intermediate years may be taken as proportional to the age.

**631. Loss of head at entrance.** The flow formulas which have been given (Par. **605** to **629**) take into account only the head necessary to overcome friction. There is in addition to this a further loss of head in creating

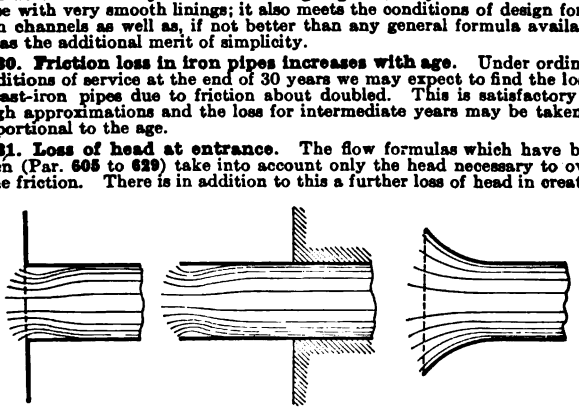

FIG. 54a. FIG. 54b. FIG. 54c.

the velocity of flow and in overcoming the resistance of entrance into the pipe. The **velocity head** is equal to $V^2/2g$. The head lost at entrance varies with the form of entrance and is expressed as a constant times the velocity head $\xi_e V^2/2g$. Values of $\xi$ are given below.

$$0.5\frac{V^2}{2g} \qquad (0.11 \text{ to } 0.02)\frac{V^2}{2g} \qquad 0.93\frac{V^2}{2g}$$

**632. Nozzles,** properly designed, furnish one of the simplest and most accurate methods of measuring small quantities of water. Coefficients of discharge for various forms of nozzles from about $\frac{1}{4}$ in. to 5 in. have been determined with great accuracy by John R. Freeman.* Nozzles are especially useful in measuring the discharge through pipes, fire hose, and in testing the performance of pumps and impulse water wheels. With nozzles to which Freeman's coefficients are applicable, discharge measurements can be made with an error not exceeding 2 per cent.

**633. Loss of head due to bends, elbows, valves, etc.** Experimental data are either meager or lacking from which to compute the loss of head due to bends, elbows, valves, etc. Their effect only becomes important with high velocities and may be considered as corresponding to so many additional

* *Trans.* Am. Soc. C. E., Vol. XXI, pp. 303–482.

Digitized by Google

feet of straight pipe. In long uniform pipe lines laid with easy curves the friction loss predominates and the minor losses may be neglected. The following table gives approximate values determined by experiments made by the Inspection Department of the Associated Factory Mutual Fire Insurance Companies, and may be used when no exact information is available:

| Name of fitting | Number of feet of clean, straight pipe of same size which would cause the same loss as the fitting. (Loss in straight smooth pipe as given by Weston). |
|---|---|
| 2.5-in. to 8-in. long-turn ells | 4 |
| 2.5-in. to 8-in. short-turn ells | 9 |
| 3-in. to 8-in. long-turn tees | 9 |
| 3-in. to 8-in. short-turn tees | 17 |
| 1/8th bend | 5 |

**634. Freeman's formula for nozzles** is given as follows:

$$G = 29.83\ Cd^2\sqrt{\frac{P_e}{1-C^2\left(\frac{d}{D}\right)^4}} \quad \text{(gal. per min.)} \qquad (121)$$

where $G$ = discharge in gallons per minute, $C$ = coefficient of discharge, $d$ = diameter in inches of the nozzle orifice, $D$ = diameter in inches of the piezometer ring at the base of the nozzle, and $P_e$ = piezometer reading in pounds

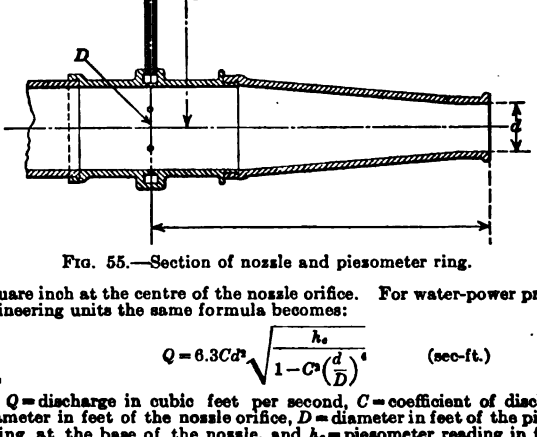

FIG. 55.—Section of nozzle and piezometer ring.

per square inch at the centre of the nozzle orifice. For water-power practice in engineering units the same formula becomes:

$$Q = 6.3Cd^2\sqrt{\frac{h_e}{1-C^2\left(\frac{d}{D}\right)^4}} \qquad \text{(sec-ft.)} \qquad (122)$$

where $Q$ = discharge in cubic feet per second, $C$ = coefficient of discharge, $d$ = diameter in feet of the nozzle orifice, $D$ = diameter in feet of the piezometer ring at the base of the nozzle, and $h_e$ = piezometer reading in feet of water above the center of the nozzle orifice.

Digitized by Google

**635. Coefficients for nozzles.** A value of 0.974 may be taken as a suitable coefficient ($C$) for the ordinary smooth fire nozzle with a nominal diameter between 0.75 in. and 1.375 in. and under pressures varying from 20 to 100 lb. per sq. in. For pressures less than 20 lb. per sq. in. the same coefficient may be used, but without so great a confidence in the accuracy of the result. For larger sizes of smooth nozzles ranging from 1.75 in. and 2.5 in. Freeman's coefficients lie between 0.987 and 0.999 for pressures ranging from 15 to 55 lb. per sq. in. For smooth nozzles from 2.5 in. up to 6 in. and under heads of more than 10 ft., Freeman suggested a coefficient of 0.995. The following coefficients have been obtained by experiment for a set of specially made smooth **meter nozzles** (Fig. 56): 2.5 in., 0.98; 3 in., 0.985; 4 in., 0.99; 5 in., 0.995. The coefficients will vary somewhat in different sets of nozzles and it is important to know at what point the pressure is registered (Fig. 55). If special accuracy is desired a set of meter nozzles which have been carefully rated by volumetric measurement should be used. With square ring nozzles the jet suffers contraction and the coefficients according to Freeman's experiments range from 0.65 up to 0.975 according to the proportions of the orifice.

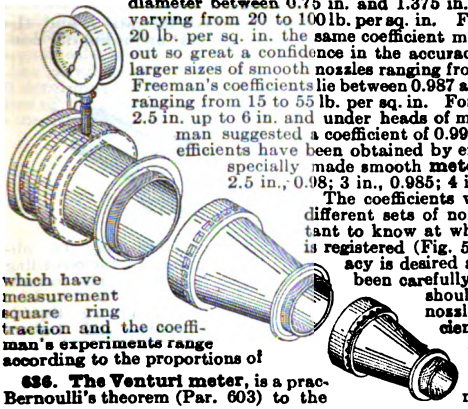

FIG. 56.—Meter nozzle.

**636. The Venturi meter,** is a practical application of Bernoulli's theorem (Par. 603) to the measurement of water in pipes flowing under pressure. The formula for discharge is

$$Q = \frac{C\pi D_b^2 D_a^2 \sqrt{2gh}}{4\sqrt{D_a^4 - D_b^4}} \quad \text{(sec-ft.)} \qquad (123)$$

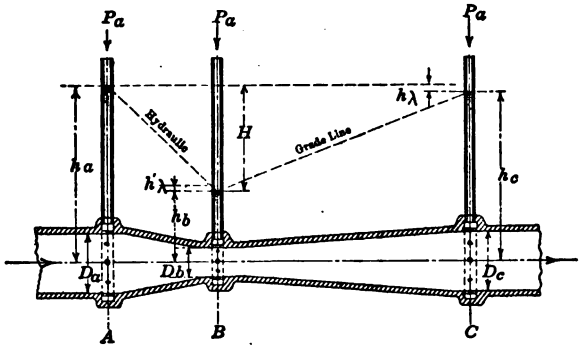

FIG. 57.—Section of Venturi meter.

The symbols will be understood by reference to Fig. 57. For meters with a given ratio of throat and inlet diameters the formula may be simplified. Let the ratio $R = D_a/D_b$ and let

$$K = \frac{\pi R^2}{4}\left(\frac{2g}{R^4 - 1}\right)^{\frac{1}{2}} \qquad (124)$$

Digitized by Google

Then $$Q = CKD_1^2\sqrt{H} \quad \text{(cu. ft. per sec.)} \quad (125)$$

| Values of $R$ = | 3.0 | 2.5 | 2.0 |
|---|---|---|---|
| Values of $K$ = | 6.338 | 6.381 | 6.505 |

The value of $C$ varies wth the velocity at the throat, the ratio $R$ and the actual dimensions of the meter. As the Venturi meters* are ordinarily constructed the coefficient $C$ is between 0.97 and 1.03. These meters may be rated backward and a coefficient of correction found to apply to the manometer reading (Fig. 58). The total loss of head through the meter tube is relatively unimportant compared with other types of commercial meters and is so small that the insertion of the meter in the mains of a water supply is rarely objectionable, and the use of this appliance is growing constantly. It may be used particularly well in high-pressure power plants where a continuous reading may be obtained by the recording apparatus; also to measure boiler feed and for measuring liquids heavier and lighter than water. Experience has shown that with the register, continuous measurements have been made with an error not exceeding 3 per cent.

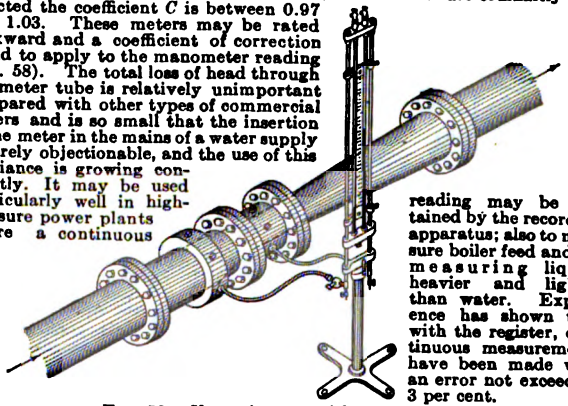

FIG. 58.—Venturi meter with manometer.

**637. The Pitometer**† (Figs. 59 and 60), by means of the differential gage registers the difference in pressure on the two orifices, one pointed directly against the current, the other in the exactly opposite direction. This difference in pressure is not a measure of the velocity head directly, but is greater than the velocity head. For these instruments the coefficient ($K$) of correction has been found to be nearly a constant, and equal to 0.84. The formula for velocity therefore becomes

$$V = K[2g(s'-1)d]^{\frac{1}{2}} \quad \text{(ft. per sec.)} \quad (126)$$

where $s'$ = specific gravity of the heavier liquid, $d$ = the deflection (Fig. 61) in feet, $V$ the velocity in feet per second, and $K$ the Pitometer coefficient. The liquid used in the differential gage is usually carbon tetrachloride and, gasoline, colored red. The specific gravity as put up for use is usually either 1.25 or 1.50 (for very accurate work the specific gravity should be determined for the temperature at which it is used). The formula (Eq. 126) then reduces to:

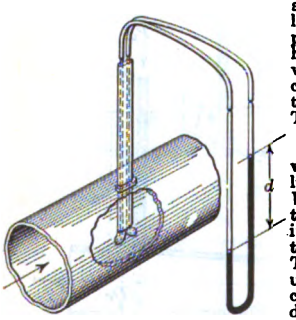

FIG. 59.—Principle of pitometer.

$$\text{For } s' = 1.25;\ V = 0.84\frac{\sqrt{2gd}}{\sqrt{4}} = 3.368d^{\frac{1}{2}} \quad \text{(ft. per sec.)} \quad (127)$$

$$\text{For } s' = 1.50;\ V = 0.84\frac{\sqrt{2gd}}{\sqrt{2}} = 5.671d^{\frac{1}{2}} \quad \text{(ft. per sec.)} \quad (128)$$

* Made by the Builders Iron Foundry, Providence, R. I., in standard sizes for pipe lines from 2 to 60 in. in diameter, and much larger sizes are in use; they may be furnished with either direct reading or recording apparatus.

To determine the discharge the cross-section of the pipe must be divided into one or more known areas (Fig. 61), the velocity for each found and hence the mean velocity for the entire cross-section; the discharge being simply the product of the area and the mean velocity. For pipes the following table (Par. **639**) is useful and the example (Par. **641**) illustrates how the discharge is calculated. The Pitometer is set so that the velocity is determined for the points as shown in Fig. 61. The pipe coefficient (see example) being first determined, it is subsequently necessary only to get a reading for the centre of the pipe and apply the coefficient to the centre velocity to obtain the mean velocity and hence the discharge by the formula:

$$Q = KCV_cA \qquad \text{(cu. ft. per sec.)} \qquad (129)$$

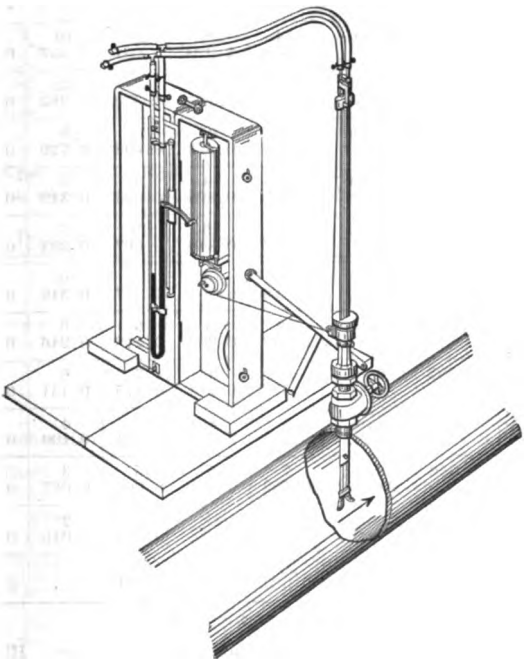

FIG. 60.—Portable pitometer.

**638. The principal use of the pitometer** is for measuring the flow in water mains where it has proved its great value in detecting leaks and waste, and in measuring the slip of pumping engines. It can be installed and operated for relatively small expense, without interfering with the flow. For large penstocks and in silt-bearing water it is not recommended. When used in old pipes, allowance must be made for incrustations reducing the cross-sectional area and a traverse of several points through more than one diameter is preferable to the single observation and the use of the pipe coefficient.

$$\frac{\text{Mean velocity}}{\text{Centre velocity}} = \frac{V}{V_c}\frac{1.97}{2.24} = 0.879 = \text{pipe coefficient.}$$

**642. Floats.** Under favorable circumstances one of the simplest methods of measuring the flow of water is by means of velocity determinations with **floats**. The different kinds of floats are surface, subsurface, or combinations of the two, and rod floats. **Surface floats**, even on a perfectly quiet day, give only the surface velocity and with any wind blowing the velocity cannot be measured with accuracy. **Subsurface floats** are but slightly heavier than water and are easily caught by eddies and cross currents which move them about in an undeterminable path and make the results unreliable. **Twin floats** have been used, but their place is better filled by rod floats.

**643. Rod floats** are cylinders usually made of metal tubing loaded with lead at the bottom so that they will float vertically with about 6 in. extending above the surface of the water. They are best adapted for use in power canals with straight, smooth sides and level bottom so that rods may be used reaching nearly to the bottom without danger of bumping. Under such conditions rod floats have been used continuously on a large scale for a great many years. The method of measurement is direct. The

* Hughes & Safford, "Hydraulics," New York, MacMillan Co., 1911, page 104.

Digitized by Google

following paragraphs are quoted from Hughes and Safford's Hydraulics (MacMillan Company):

"Procedure in measuring velocity. A straight stretch of stream should be selected as a place for gaging, and two cross-sections selected to mark the beginning and the end of the area. The float should be placed quietly in the stream at such a distance upstream from the upper of the two cross-sections, that it will be running with the current before the first marker is reached. The time of passage between these two sections, of which the distance apart is known, should be noted with a stop watch; or the position of each float at successive intervals of time be located by engineers' transits or sextants by intersection, and the points plotted on a scale drawing, from which the distance traveled in the observed interval of time can be computed. The distance in feet divided by the time of each run in seconds will give the velocity of the float in ft. per sec."

**644. "Application of rod float measurements** (Hughes and Safford). The sphere of usefulness of rod-float measurements is somewhat limited, and the expense of making them is relatively great. Their regular use in the future will probably be limited to straight, deep canals or flumes where a high degree of accuracy is required, where a sufficient force of men is regularly employed for this and other purposes, and where it is very necessary to gage all the water used for power and other purposes, without interfering with the operation of the mills. Ordinarily, the difficulty of getting good results from the sum of individual measurements, or readings of water wheels, is due to the fact that the total discharge, which is simply the sum of the individual water wheels, often does not include the leakage or the water used for manufacturing purposes other than power; but the flume measurements of the total quantity passing to each mill will cover everything. There is very little opportunity to make such measurements in rivers or canals which do not have a regular cross-section; and for such conditions there is no question that measurements by current meter (Par. **662** to **665**) will take the place of those formerly made by rod floats. The most notable published gagings by rod floats are those by Humphreys and Abbott of the Mississippi River, those described by James B. Francis in the Lowell Hydraulic Experiments, Darcy and Bazin's gagings, and the gagings of certain rivers in India."

**645. "Limits of accuracy in use of rod floats** (Hughes and Safford). With a straight, smooth flume of great depth, and velocities ranging from 2 to 5 ft. per sec., quantities of water from a few hundred to 4,000 cu. ft. per sec. have been repeatedly measured with a probable error of 1 to 2 per cent. This form of measurement, which in its successive steps gives the product of the cross-section and the velocity of the water as indicated by the rod floats, is a perfectly natural one; and its simplicity appeals to the non-technical man."

Rod floats cannot be run with the lower end closer than 2 or more in. from the bottom. Some correction must be made to account for this slower layer of water which does not act on the float. The following formula was derived by James B. Francis by comparing rod float measurements with a weir:

$$C = 1 - 0.116\,(\sqrt{D} - 0.1) \qquad (130)$$

where $C$ = a coefficient of correction which multiplied by the observed velocity will give the corrected velocity, and $D$ = difference between the depth of water in the flume and length of immersed part of tube, divided by depth of water.

## STREAM FLOW

**646. The local variation of the average annual rainfall** in the United States is all the way from nothing in some years in the desert regions, to an

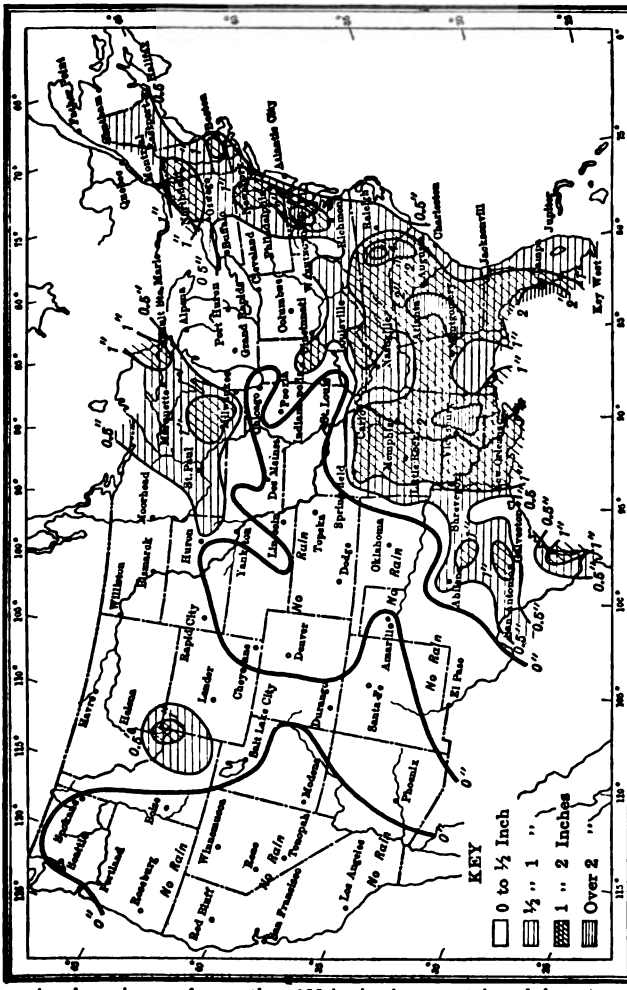

Fig. 62.—Map of United States showing distribution of rainfall.

occasional maximum of more than 100 in. in the mountains of the extreme northwest. An examination of the map in Fig. 62, will give an idea of the

Digitized by Google

geographical distribution of rainfall over the United States as affected by altitude, climate, proximity to the ocean, etc. In general mountain ranges receive a greater amount of precipitation than the surrounding valleys and yield a greater proportionate run-off.

**647. Source of run-off.** Rain or snow falling on the drainage areas of rivers is the immediate source of water power. The relation between the rainfall and the run-off is a direct one; rain falls on the ground and a part of it finds its way to the water courses, and yet there are so many physical factors affecting the disposal of rainfall that to establish the relation between it and run-off is baffling if not actually impossible. The cycle of rainfall and run-off is complete when we include the evaporation of moisture in the form of vapor from water and ground surfaces, to fall later as rain.

**648. Rainfall records.** The U. S. Weather Bureau has kept rainfall records at stations geographically widely distributed for a long period of time and it frequently occurs that good rainfall records are at hand when no stream gagings can be obtained. For this reason, any relations, even only approximately fixed, between rainfall and run-off are of considerable value to the water-power engineer.

**649. The main factors affecting the disposal of rainfall** are the topography, geology, evaporation and the amount taken up by vegetation. Rugged drainage areas with steep slopes discharge the water readily and quickly into the water courses. Rivers draining such areas, unless there is good storage in lakes and ponds, are more subject to sudden fluctuations in flow than rivers draining flat or rolling country where there are many swamps and where the water has chance to sink into the pervious soil. Evaporation, according to our best present knowledge, is essentially the same from year to year in any one locality and likewise the amount of moisture taken by the vegetation is about a constant.

**650. Run-off** is the result of rain falling on the contributing drainage area and is subject to the same conflicting influences, with an additional factor of great importance, which is the degree of water-storage development on the river. We can measure and know the rain at any one or a number of points and form a more or less close estimate of the total rainfall over the whole area. We can measure and know the evaporation from water surfaces with fair precision. For the rest it is mainly conjecture, though we can count on vegetation to take a fairly constant amount of moisture from year to year and over large sections of the country. In a year of small precipitation, the evaporation will be at least normal, vegetation will require as much as usual and take all it can get, with the combined result that the run-off of the rivers will get a smaller proportion of the total rainfall than in years of average or excess precipitation. For these reasons, it is very difficult to use any percentage ratio between run-off and precipitation.

In the case of water powers already established where run-off records are kept, a knowledge of the local relation between rainfall on the contributing area and the flow may be very valuable from an operating point of view. Of course if there are gaging stations up river these give more direct and reliable information. It is only in the absence of gaging stations that estimates based on the amount of rainfall need be resorted to, and then must be used with the greatest care.

**651. Distribution of run-off.** For comparative purposes it is convenient and advantageous to express the flow of rivers not by total flow, but in cu. ft. per sec. per square mile of drainage area. The following is a list of the major factors influencing the distribution of run-off:

(*a*) Geology—is the soil pervious or impervious (Par. **652**).

(*b*) Topography—is the drainage area flat or rolling, or has it steep precipitous slopes (Par. **653**).

(*c*) Size of the contributing area (Par. **654**).

(*d*) Climate—amount and distribution of rainfall and evaporation (Par. **655**).

(*e*) Storage—whether natural or developed—the degree of development and the location of the storage basins (Par. **656**).

These cannot be said to be of equal importance and the relative effect will differ on different areas. It will be seen that the fifth factor only can be altered by man, and looked at in this light it assumes an importance of greater moment than the rest. An even distribution of the run-off is a most desirable

Digitized by Google

characteristic. Taking up in order the main factors listed above we shall see how each one affects the distribution.

**653. Geology.** Pervious soil will allow the water falling on it to percolate down into it, where it is held as ground water, a part to find its way into the streams when the general water table is lowered. If the soil is impervious water must run off quickly and find its way to the main water courses. Thus heavy storms of short duration falling on frozen or saturated ground will cause sudden rises in the stream and much water may be wasted.

**653. Topography.** Flat or rolling country combined with a pervious soil is admirably fitted to hold the rain in storage as ground water. The precipitous, rocky slopes are equally fitted to discharge the rain almost as it falls and do nothing to even up the distribution of run-off. But if complete or nearly complete water storage is provided, a precipitous drainage area may be better for water-power purposes than more level country. Between the two conditions are a multiplicity of possible combinations and effects.

**654. Size of drainage area** has an additional influence when there is little or no storage available. This is because the variation in the extent and intensity of rain storms is extreme. A local storm of sufficient intensity to cause a freshet on a small area, occurring on a drainage area of a thousand square miles or more would hardly be felt on the main river. It is for this reason that without storage small rivers show much greater divergence between maximum and minimum discharge. This would to some extent be off-set by a complete forest cover, which on the small stream would undoubtedly delay the peak of the flood and might entirely prevent a sudden rise. It can never, however, hold the water in storage like a reservoir, to let it down at certain seasons of the year. Furthermore on drainage areas of considerable size sufficient areas usually cannot be deforested or grow up fast enough to have an effect more than local.

**655. Climate.** The climate prevailing on a drainage area will depend on its geographical location and on its topography. It is sufficient here to refer to but two aspects: (*a*) the total annual precipitation and its distribution; (*b*) the total evaporation (Figs. 65 and 68) and its distribution. There is such radical variation in different parts of the country that no general discussion will be attempted here. Every case must receive careful study to ascertain the local conditions and tendencies. A map of the United States is given in Fig. 62 showing the distribution of the average annual precipitation over the country.

**656. Storage** may exist on streams and rivers naturally in the form of swamps and lakes, or may have been developed by damming up streams at favorable points, or in raising lakes already in existence. The degree of development of the storage on a drainage area is important. If underdeveloped there will be a waste of water during the periods of high water which, if held in storage for future use, would greatly enhance the value of the reservoir. The storage on a drainage area may be said to be completely developed when the reservoir fills once in each normal year without much waste, and is of sufficient capacity to carry over a series of two or three dry years with undiminished yield, but without filling entirely; of course such cases are rare. Two examples in New England are the Winnipiseogee river which drains the lake of that name in New Hampshire, and the Presumpscott river flowing out of Sebago lake in Maine. Lake Winnipiseogee (Par. **657**) has an area of approximately 70 square miles with a drainage area exclusive of the lake surface of about 300 square miles. The steady yield of this lake with rare exceptions is from 1.5 to 2 cu. ft. per sec. per square mile. Sebago lake has a surface area of about 50 square miles and a contributing area of about 420 square miles. The flow at the outlet of the lake rarely falls below 1.6 cu. ft. per sec. per square mile on week days.

Perhaps the most **advantageous location** for storage reservoirs, if not too large for their contributing areas, is near the head waters of a river, for in that way all powers are benefited. The most economical **method of handling** the storage will vary in different cases; usually the water is let down quite uniformly throughout the year. There are cases, however, where the best way is to keep the storage gates closed most of the year and then draw heavily during the dry season. This method is the desirable one to follow when the total area of the river basin is large, the water storage great, and the area contributing to the reservoir a small part of the whole. The

Digitized by Google

whole object of storage is to keep up the flow of the river as well as possible, in order to make as high as may be the permanent dependable power. Every reservoir and mill pond on any stream must be operated subject to the legal rights of others on the stream. In any particular case the yield of a reservoir may be predicted from a study of the run-off of the contributing area, the precipitation on and the evaporation from the water surface. Trial drafts from the storage are assumed and the effect traced through a number of years. In this way very safe estimates can be made of the storage yield.

**657. Example of a large storage basin.** The following figures show by way of illustration the condition of Lake Winnipiseogee (Par. **656**) on May 1, Aug. 1, Nov. 1, and Feb. 1, using 1911 and 1912 figures of run-off and precipitation, and average figures of evaporation. The yield of the contributing area is expressed in inches of depth on the lake area, rainfall and evaporation are given directly in inches and the draft, 600 cu. ft. per sec. throughout the year, is also reduced to in. of depth on the lake area for each month.

| Date | Yield of the contributing area expressed in in. of depth on the lake area for the month | Rainfall in in. during the month | Evaporation in in. during the month | Draft 600 cu. ft. per sec. expressed in in. of depth on the lake area for the month | Net gain or loss in in. of depth on the lake area for the month | Elevation of the lake* |

**658. River gaging stations** are maintained by the U. S. Government and the State Governments on many rivers and streams throughout the country. This work of gaging the rivers is carried on by the U. S. Geological Survey, Dept. of the Interior, and the observations and results are published. These publications, which are invaluable in studying the possible water-power development of our streams, may be obtained at nominal expense from the Supt. of Documents, Government Printing Office, Washington, D. C.

**659. Flow in open streams** is subject to the same laws as the flow in any other channel (Par. **602**), but because of the irregularity of section and the changing character of the bed from point to point the difficulties of finding a formula to fit all conditions are manifold. The only reliable data concerning discharge of a stream are based on actual measurements.

**660. Measurement of stream flow.** The method adopted will depend largely on the size of the stream, its cross-section and the variation between minimum and maximum flow. A weir can be successfully used in a small stream discharging a few cu. ft. per sec. and is largely employed in irrigation ditches. For rivers from medium to large size the most adaptable method is to employ a current meter and by making measurements at several stages of flow establish a **rating curve** by means of which it is only necessary to read a gage, compare the reading with the rating curve and find the

Digitized by Google

discharge corresponding to the given stage. The same rating curve cannot be used for both winter and summer conditions.

**661. Typical hydrographs** showing the monthly average stream flow in sec-ft. per square mile of drainage area are shown in Figs. 63 and 66, for the Kansas (Kan.) and Columbia (Ore.) rivers respectively. Figs. 64 and 67 show the accompanying monthly rainfall in typical years. Figs. 65 and 68 show the accompanying monthly evaporation. These stream-flow records or hydrographs naturally exhibit different characteristics according to the local climatic and other conditions, as noted by comparing Fig. 63 with Fig. 66, and Fig. 64 with Fig. 67. Furthermore, the hydrographs of the same river vary materially as a rule from year to year, between rather wide limits; Figs. 63 and 66, besides showing the stream flow for typical years, also show the maximum (wet year) and minimum (dry year) flow observed during a series of years. It is also instructive to compare the records of rainfall with those of stream flow; compare Figs. 63 and 64, and Figs. 66 and 67. Similar records and charts should be obtained for any particular river or stream, if possible, in connection with consideration of its water-power possibilities.

**662. Current meters** may be roughly divided into two classes, those in which the wheel revolves about a vertical axis and those in which the axis is horizontal.

The Price-Gurley meter (Fig. 69) belongs to the first class and is the type adopted by the government in its stream gaging work. It is fitted with a vane to keep it headed into the current and with an electric sounder to enable the operator to record the revolutions without taking the meter from the water. This meter can be slung from a cable and operated from the shore or from a bridge, or from a car suspended from a cable. In shallow water the meter is attached to a rod and operated directly by hand. The disadvantage inherent in this meter is that it always records the maximum velocity, whether that velocity is in a forward direction or is merely caused by cross currents and eddies; all alike are recorded as forward. Consequently this meter has a tendency to give results which are too high.

The Haskell meter (Fig. 70) is of the screw-propeller type and operated in the same manner as the Price-Gurley meter. It is subject to the same criticism in that it records the maximum velocity at the point of immersion regardless of its direction.

The Fteley-Stearns meter (Fig. 71) was designed for use in the Sudbury Aqueduct of the Boston Water Works and is especially adapted for use in

Digitized by Google

flumes or any channels where it is desired to get the velocity close to the sides and bottom. It is ordinarily fitted for use on a rod and is equipped with recording dials thrown in and out of mesh by a cord. The meter can also be fitted up with vane and electric sounder. It then loses its peculiar value in recording only the forward component of the velocity of the water, which makes it a true integrating instrument. It has been successfully used in large rivers and in velocities from 0.4 to 10 ft. per sec.

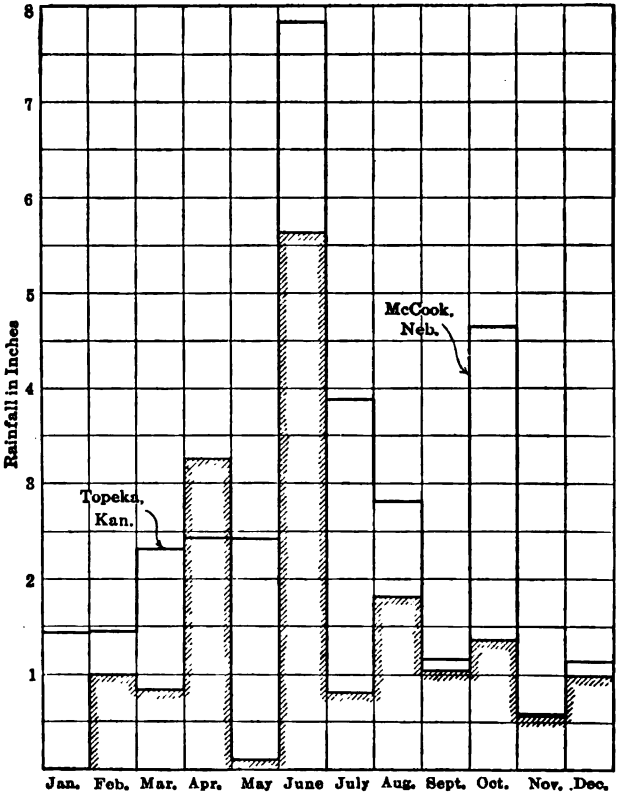

FIG. 64.—Monthly rainfall in Kansas River valley, 1897.

**663. Water wheels as current meters.** Water wheels if rated to determine their discharge with given head, gate opening, and speed, are in common use as water meters in power plants. If occasionally checked by rod float or current meter measurements they are quite accurate enough to base the use or sale of water on the quantities so determined. The Holyoke test (Par. **706**) of a wheel gives the necessary information from which a discharge rating curve may be constructed, but it is more satisfactory if in addition to this, careful measurements are made with the wheels in place.

Digitized by Google

**664. Methods of using current meters** are as follows:
(*a*) Single point at 0.6 depth.
(*b*) Two points at 0.2 and 0.8 the depth.
(*c*) Multiple point.
(*d*) Integrating: (1) vertically; (2) diagonally.

The single point method at 0.6 depth (*a*) is supposed to give the average velocity of the vertical section in which it is held. Except in special cases such as natural streams uncontrolled by local conditions this can rarely be relied upon.

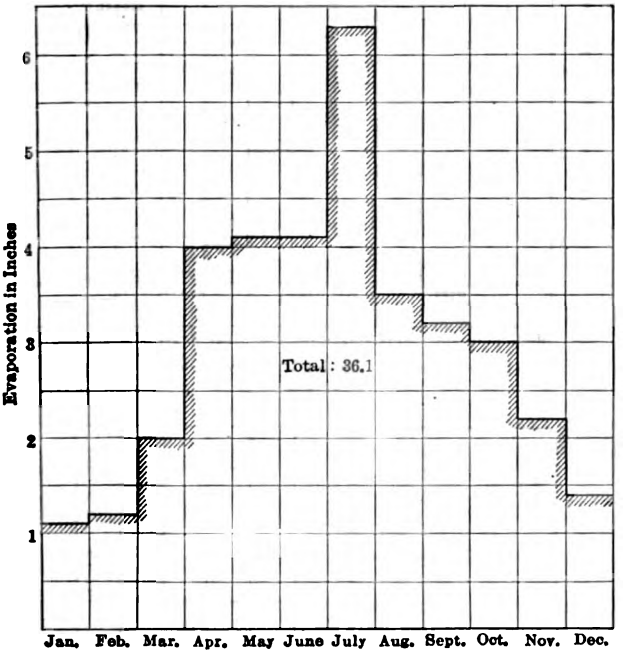

FIG. 65.—Monthly evaporation of Topeka, Kan., July, 1887–June, 1888, computed under the direction of T. Russell, U. S. Mo. Weather Review, Sept., 1888.

The average of the two velocities at 0.2 and 0.8 depth (*b*) is supposed to give the mean velocity of the vertical section in which it is held. The same comment applies.

These two methods have been advocated by the government service for quick measurements but are not recommended for accurate work, without actual determinations of velocity distribution in the stream cross-section.

By dividing the cross-section into several imaginary vertical strips of width depending on the total width of the stream and the uniformity of flow, and measuring the velocity at several points in each vertical strip the true mean velocity can be closely approximated. This method (*c*) is recommended for use in power canals where the flow is fairly steady so that during the time consumed in making the measurement there is no material change. It is

Digitized by Google

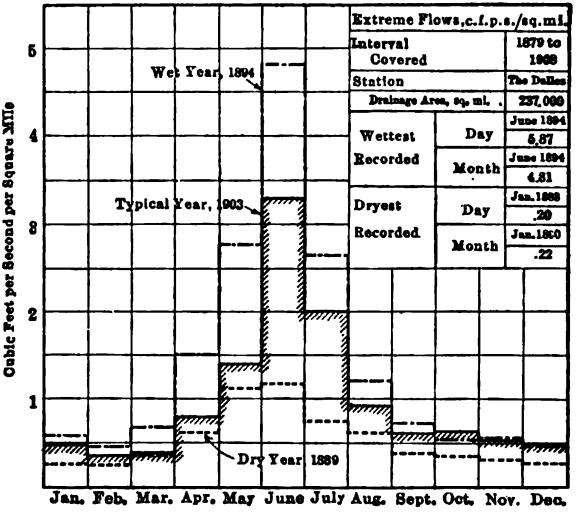

FIG. 66.—Hydrograph of Columbia River from records of The Dalles, Oregon.

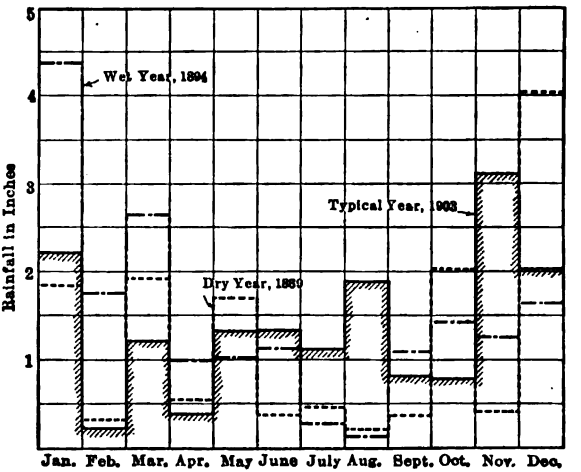

FIG. 67.—Monthly rainfall at Spokane, Wash.

Digitized by Google

especially useful in showing the distribution of the velocity over the cross-section.

Vertical integrating measurements (*d*) (1) are made by slowly lowering the meter from top to bottom and raising it again along the same vertical path. In this way the average velocity for the stripe in order is obtained mechanically. In diagonal integration (*d*) (2) the meter is moved slowly across the stream at the same time it is being lowered and raised. By this method the mean velocity for the entire cross-section of the stream is obtained in one continuous operation.

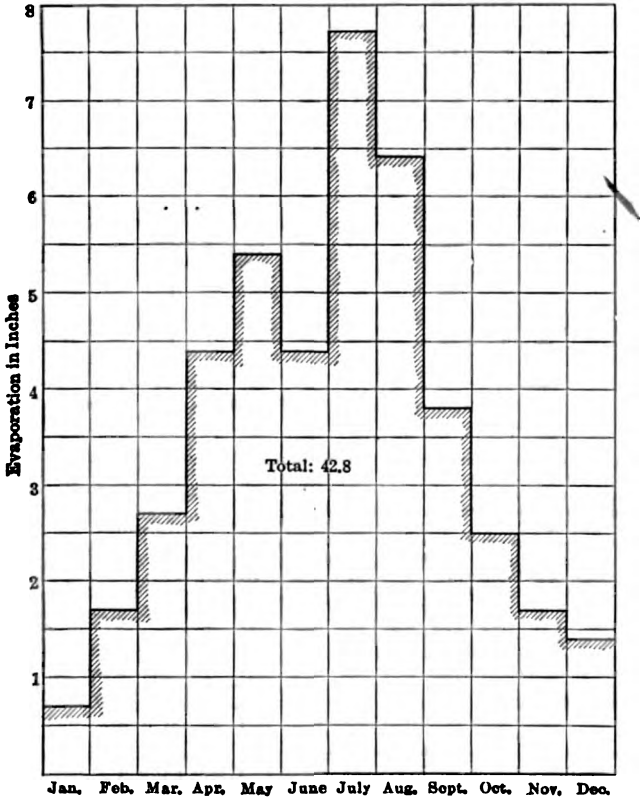

FIG. 68.—Monthly evaporation at Spokane, Wash., July, 1887–June, 1888, computed under the direction of T. Russell, U. S. Mo. Weather Review, Sept., 1888.

**665. Choice of method.** The width of the channel, the conditions of flow and the degree of accuracy desired are important considerations in

Digitized by Google

selecting the method to be used. By dividing the stream cross-section by verticals into areas of equal width, through the centre line of which the meter is lowered and raised with uniform speed, the mean velocity in ft. per sec.

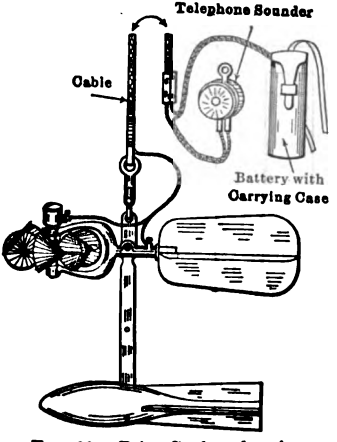

FIG. 69.—Price-Gurley electric current meter.

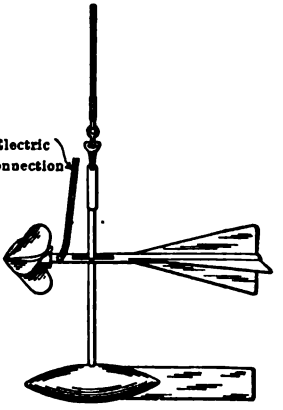

FIG. 70.—Haskell current meter.

for each section is obtained in one operation. This method is on the whole to be preferred for determinations of discharge. The multiple-point method is of great value in determining the distribution of velocity in any cross-section, which is often necessary for at least one gaging; but for determination of discharge this method is tedious and if the stream is subject to fluctuation in stage it is too slow.

If the channel is not too wide or deep the diagonal integration which covers the whole stream in one operation is a very satisfactory form of measurement because it permits a great many measurements under different conditions and avoids many disturbing conditions. Its use is limited by the endurance of the operator. The double-point and single-point methods are only rough approximations, but serve a useful purpose in securing information of stream flow at low cost.

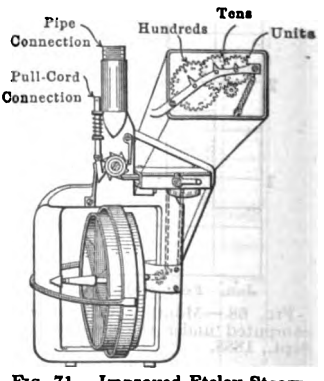

FIG. 71.—Improved Fteley-Stearns current meter.

**666. Effect of ice.** Ice cover on a stream or canal decreases the cross-section, and increases the wetted perimeter or rubbing surface. Both of these result in additional loss of head, the first through increasing the velocity, the second through increasing the frictional resistance to flow. In power canals the formation of an ice cover of sufficient thickness to last through the cold season is a protection against troubles from anchor ice and frazil ice. Neither anchor ice nor frazil ice

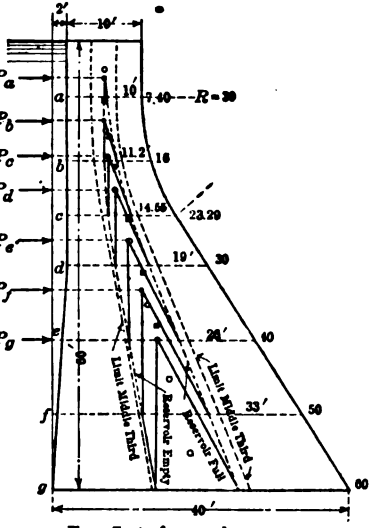
Digitized by Google

will form under an already existing ice cover; the latter is therefore desirable and canals should be designed with this in mind, and the velocities should be kept down (2 to 3 ft. per sec.) by making the cross-section ample for extreme conditions. Anchor ice is ice which forms on the bottom of the stream or canal and may seriously obstruct the flow. Frasil or needle ice forms, as the name implies, in small needles where the current is too rapid for the formation of surface ice. It may either attach itself to the bottom or to anchor ice already formed or it may be carried against and effectually clog the racks of a power house.

## DAMS AND HEADWORKS

**667. Water storage** has already been referred to in Par. **656** and a method outlined for testing out the dependable constant yield. The value of a storage reservoir increases rapidly as the capacity per square mile of contributing area increases up to 15,000,000 cu. ft.; beyond that point there is likely to be a slower rate of increased yield for a given increase in capacity per square mile of drainage area. 75,000,000 cu. ft. per square mile might be an overdevelopment of storage.

**668. Pondage,** as the term is used here, means the water impounded directly by the power dam and is therefore almost always formed by backing up the river itself. The study of pondage and its proper handling is complicated in the general case, but as a rule comparatively simple of solution for any actual power plant. The reason is that it is involved with the load curve, the natural and legal restrictions of the flowage permissible, and flow detained, and the variation in head economically advisable. Granting the possibility and rights of pondage, the problem reduces to a consideration of fitting the use of water to the demands for power made on the station. If the station carries a typical combined power and lighting load, pondage is essential to satisfactory operation since the great demand for power is during the day-time and the early evening hours. If the head may be drawn down during the day so that the pond will be just filled up by the night flow, the most that is possible is being obtained from the river.



For effect of upward pressure see Spillway Dam

FIG. 72.—Reservoir dam.

In some cases of low-head and medium-head developments the advisable reduction in head is the controlling or limiting factor. As the head falls the power and efficiency of the water wheels fall if the speed is kept up, as it must be in hydroelectric stations. Foresight and study of the probable range of head variation make it possible to have wheels designed with characteristic curves specially suited to the case and a greater variation of head may be permitted.

**669. Dams,** regardless of the material composing them, may be roughly classified into two main divisions: (*a*) Impounding dams for holding water back, as in a reservoir, but which are not designed to have any water pass over them; (*b*) spillway dams or sections.

Digitized by Google

**670. Impounding dams** (Fig. 72) are almost invariably of the gravity type depending on their own weight to resist the forces of the water except in the rare cases where curved dams have been built depending wholly or in part on arch action. The present practice is tending toward heavy earth dams.

**671. Spillway dams** (Fig. 73) may be further subdivided into gravity types and those depending, through their design, on the hydrostatic pressure of the impounded water to hold them against the river bed, and arch dams. The arch dam is very economical of material but requires that the abutments be founded in strong solid material capable of taking up the thrust.

Limit Middle Third
Limit Middle Third
Resultant without upward pressure
Resultant with upward pressure
Assumed distribution of upward pressure
Distribution of resultant pressures (with upward pressure as assumed)
Distribution of resultant pressure (assuming no upward pressure)

FIG. 73.—Spillway dam.

**672. Coffer dams** according to their height, the nature of the bottom and the exposure of the location to current or wave action are constructed in a great number of ways. Some of the more common methods are mentioned. Interlocking sheet steel piling, and single or double rows of wooden sheet piling with a puddled filling between the two rows, are forms frequently used. For low cofferdams the A-frame covered with gravel; or bags half filled with sand piled in careful rows have been successfully employed. The design of cofferdams is based on the same principles of hydrostatics governing the design of any other dam.

**673. Design of dams.** The conditions which should be safely met by all dams are stated briefly as follows: (*a*) the dam must not slide; (*b*) the dam must not overturn; (*c*) the dam must not crush. The external forces acting are the water pressure, the weight of the material composing the dam, the reaction of the foundation, ice pressure near the top, and wind and wave pressure. The pressure usually figured is that of the greatest known freshet, on the toe of the deepest section, without backwater. The cross-section of the dam is determined by trial. A tentative section is assumed and then all the forces are computed. If the dam as first designed cannot satisfy all the conditions of safety or is unduly heavy it is modified accordingly.

In the case of the high dams of the gravity type (Fig. 72) it is customary to assume the dam divided by horizontal joints, the depth of each section chosen according to judgment in each case, and to treat the sections arbitrarily so selected progressively beginning at the top, testing each for sliding, overturning, and crushing. In this way a resultant line of pressure may be traced. In the design of masonry dams it is customary so to proportion the section that the resultant pressure at all horizontal joints shall fall within the middle third whether the reservoir be full or empty. This gives a factor of safety of two against overturning, and there will be no danger from tensile stresses on the face of the dam.

There is rarely any trouble experienced, when proper construction methods are used, from sliding within the body of the dam itself. The joint between the dam and its foundation is the critical point at which to guard against sliding. It is in this connection that the amount of upward pressure becomes of vital importance. On ledge foundations, steps or trenches should be cut to ensure a sufficient bond. On poorer foundations the dam must

Digitized by Google

be made massive enough to safeguard against sliding by keeping the angle between the resultant pressure on the base and a vertical line, less than the angle of sliding of the foundation material. There is no danger from crushing in dams otherwise stable, except in very high dams which are not treated here.

Dams which depend on the hydrostatic pressure of the water to hold them in place (Fig. 74) may be made much lighter than the solid masonry dams. The principal calculations for strength involve the deck treated as a reinforced slab and of the buttresses as walls subjected to simple compression. Fig. 74 illustrates the action of the resultant pressure. If a floor is used weep holes are provided to allow any seepage to escape unobstructed.

For a more thorough and comprehensive treatment of dams reference should be made to chapter XXIX. "Principles of Construction of Dams" in "Water Power Engineering," D. W. Mead (McGraw-Hill Book Co.) and to "The Design and Construction of Dams," Edward Wegmann (Wiley & Son).

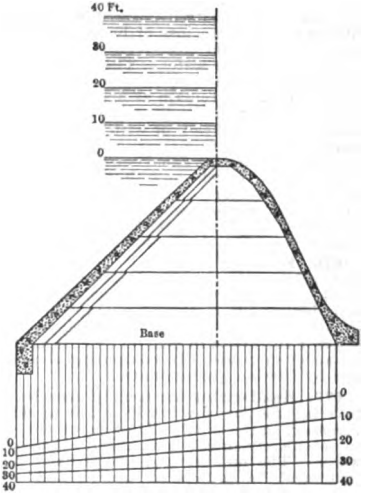

FIG. 74.—Concrete-steel dam.

**674. Upward pressure on the base of a gravity-type dam** (Fig. 73) should receive most careful study. The limiting conditions are, on the one side, a tight impervious bottom with the dam so set and keyed into it that no leakage can occur under the dam. This in effect assumes an unbroken, water-tight wall extending from below the bed of the river up to the crest of the dam. The other extreme would be a dam founded on loose gravel or porous rock which freely admitted the water under the entire base of the dam, but at the downstream toe a cut-off wall would prevent the water from escaping.

In the first case the assumption is no upward pressure whatever, in the second there would be pressure due to the full hydrostatic head uniformly distributed over the base of the dam. Rarely, if ever, can either of these cases be found in the extreme form suggested. The truth in every case is doubtless between the two. In other words there is probably no dam existing without some upward pressure, its extent to be determined only by a most careful examination of the geological formation of the river bed at the dam site and the thoroughness with which the seepage is cut off by cut-off walls, grouting or other preventive measures. Except in those cases where the dam is founded on ledge rock which gives undoubted evidence of soundness and extent, borings are the essential preliminary to the study and design of a dam. No rule can be given as to the number of borings necessary but in a general way there should be enough to cover the area not only of the spillway section in the river bed, but also of the abutments and wing walls; and other structures near the river; undermining here may prove quite as disastrous as under the spillway section.

In the case of pervious foundations it is desirable to carry a cut-off wall or spiling at the upstream toe down to an impervious stratum. Where such does not exist the wall should be carried to such a depth that the friction opposing the flow of water will render the seepage under the dam inappreciable. It is good practice in designing and building dams to eliminate so far as is possible the leakage which causes upward pressure, but to assume in

Digitized by Google

the computations for stability the existence of full upward pressure at the upstream side diminishing uniformly to zero at the downstream toe.

**675. The design of canals for power purposes** should be made from an economic viewpoint. Canals are employed to utilise a greater head than is obtainable directly at the dam and must be built to give the greatest benefit at the least cost. Head, the very object of the canal, is often unnecessarily lost through poor design of the cross-section and alignment, or through permitting unnecessary roughness of the bottom and sides. Some slope will be required to carry the water through the canal. This should be provided by the canal bottom itself unless the drainage must be in a contrary direction; otherwise an extra loss of head will result, for the slope of the water will reduce the stream cross-section and necessitate a higher velocity to pass a given quantity of water. The form of the cross-section must be determined by its requirements and the character of the material. The form should be such that it will remain as first built and not wash or slide. In general the relatively wide and shallow canals should be avoided because with any drawing down of the head, or with an ice cover the net area suffers a greater proportionate reduction than in the case of deeper, narrower canals. The advantage of the deep canal can also be shown from a consideration of the formulas for flow, which show that for a given area the section with the smallest wetted perimeter will give the best results. The velocity should be kept low and as uniform as possible. If there are changes they should be made gradually and in general a velocity once gotten up should be held. The same statements apply to ditches whether for irrigation or power.

**676. Flumes.** The word flume implies a narrow waterway with vertical or nearly vertical sides. It was formerly used to designate the canal or penstock conveying water to the wheels at its end. In modern practice a flume is understood to mean an aqueduct of relatively small dimensions constructed usually of timber or concrete employed to carry water long distances. The interior surface is in general smooth and water is carried at a high velocity on an even grade. In computing the carrying capacity of such structures loss by friction predominates.

**677. Head-gates** are usually installed at the entrance to a canal to control the amount of water let in, or to shut it off entirely in case repairs are necessary in the canal. They should be strong enough to permit the water to be entirely drawn out of the canal and to protect the plant during high water. The number and size is fixed by the quantity of water and such structural limitations as weight and strength may impose. Head-gates are either hand or power operated according to local circumstances; but modern requirements are demanding motor hoists. In designing the piers it is usually well to provide for stop logs for occasional repairs to the gates. Whenever possible the gates should be so set that the water from the river enters at low velocity without sharp contraction or change in direction.

**678. Booms** either floating or fixed are usual to prevent floating débris from reaching the head-gates, and in northern rivers ice is also diverted over the dam or through special iceways by this means.

**679. Penstocks** are frequently used instead of canals or in conjunction with them, the choice depending on cost in the case of low-head to medium-head plants. In high-head plants penstocks and pressure tunnels become the only way for conveying water from high elevations down to the power house. Penstocks are usually built of riveted steel plates, wooden staves, or reinforced concrete, depending on local conditions. They must be designed for strength and carrying capacity. Structurally they must be able to withstand the pressure due the head plus the effect of water hammer and also, when empty or partly filled, be strong against collapsing. In long penstocks great care must be taken to provide against **water hammer.** In the first place, the thickness of the shell should be selected with this in mind and, secondly, provision should be made to take care of the surges when they occur. Where the head permits, the most satisfactory protection is given by **stand-pipes** or **surge tanks.** Further protection is given by **relief valves** and **blow-out plates,** usually placed just outside the power house.

The thickness of riveted steel penstocks necessary to withstand water hammer may be computed as follows:

$$t = \frac{(p + p')r}{15000\,e} \quad \text{(in.)} \qquad (131)$$

Digitized by Google

where $t$ = thickness of the shell in inches (should never be less than 0.25 inch), $p$ = intensity of internal pressure in pounds per square inch, $p'$ = additional pressure in pounds per square inch allowed for water hammer, $r$ = radius of the penstock in inches, and $e$ = efficiency of the riveted joints which varies from 0.5 to 1.

Values of $p'$ to be used in above formula (Eq. 131)

| Nominal diameter of pipe (in.) | $p'$ (lb. per sq. in.) | Nominal diameter of pipe (in.) | $p'$ (lb. per sq. in.) |
|---|---|---|---|
| 16 and 18 | 100 | 30 | 80 |
| 20 | 90 | 36 | 75 |
| 24 | 85 | 42 to 60 | 70 |

In designing penstocks for carrying capacity, the velocity to be allowed will depend, as in the case of canals, on the value of the head saved by additional expenditure in the original construction. The problem must be studied in the light of this consideration and the size of penstock selected accordingly.

**680. Cost data.** The cost per developed kilowatt of different hydraulic structures varies very much with the type and character of the development; and is relatively less where the power can be generated near the dam or the output is large by reason of a high head or a large dependable flow. A typical development representing fairly average conditions for a built up fall is:

| Item | Per cent. of total cost | Cost per kilowatt on 25,000 kw. equipped |
|---|---|---|
| Property | 19.3 | $24.00 |
| Dam | 11.6 | 14.50 |
| Canal | 42.3 | 52.60 |
| Power house and foundations | 9.6 | 12.00 |
| Equipment | 17.2 | 21.40 |
| Total | 100.0 | $124.50 |

Note that the cost of the canal in this case is two-fifths of the entire cost; but this is usually the case unless a portion of the fall is left undeveloped.

Steam relay, to supplement dry-weather flow, will add 30 per cent. more to the total cost.

**681. Forebay and racks.** The forebay, where water wheels do not draw directly from the canal or penstock, is an enlargement of the canal leading directly to the racks of the power house which is built across the lower end. The power house should be set so that the water flows from the canal and passes through the racks with slight if any change in direction. There is necessarily some loss of head in getting the water through the racks and this should be minimized by setting them so that they draw the water directly, as mentioned. Provision must be made by a waste weir and channel so placed that when open a strong surface current will be created making it easy to float accumulated débris and ice away from the racks and discharge them into the river.

Racks are customarily built up of flat iron bars from 1/4 to 1/2 in. thick and 2 to 3 in. wide, spaced an inch and a half or more apart in the clear, with the flat side parallel to the flow. The spacing will depend on the size of the water wheels and the fineness of the material to be excluded. The rack should be sectionalized into panels which can readily be lifted out for repairs. They should be set at an angle of approximately 30 deg. from the vertical in order to facilitate cleaning with a rake from a platform extending the length of the intakes to the power house. They should be designed of sufficient strength to withstand the water pressure as a dam in case they become completely clogged or frosen up. In cases where every effort is made to save loss of head, rack bars are made with

Digitized by Google

rounded edges or of lenticular shape. There is inevitably some contraction of the streams of water in passing through the racks, which should be allowed for in computing the net area to be procured. The velocity through the racks should be kept low, even when partially clogged. Three feet per second should be the maximum allowed under the very worst conditions.

## WATER-WHEELS

**682. Hydraulics of water-wheels.** Force is required to change the velocity and direction of any moving body. In the case of hydraulic turbine motors water is the moving body and the water-wheel (whether impulse or reaction, or combined) is the agent by which the velocity and direction are changed and useful work derived from the process. The portion of the reduction in velocity not chargeable to friction or other losses occurring during the passage of the water through the buckets is a measure of the efficiency of the wheel as a prime-mover. If a jet of water impinges on a moving vane or bucket, assuming a condition of no friction, the bucket will acquire a velocity equal to that of the jet, *i.e.*, the theoretical velocity due the head acting. The velocity of the wheel must be considered that of the centre of application of all the filaments of water. Under this condition, where the velocity of the bucket and of the jet are the same, the jet can exert no pressure on the bucket and no work is done. Actually the bucket velocity must in any case be decreased by friction from that supposed above, and the water must exert at least a corresponding amount of pressure. If now the velocity of the bucket be further decreased until it is blocked, the water is exerting its maximum pressure but again no work is being done. There is some speed of rotation between these two extremes at which the maximum amount of work will be done; that is, the maximum portion of the velocity of the moving water will be converted into useful work. At this point the motor is running at maximum efficiency. Although the buckets and vanes may be simple or complicated, the above fundamental conception holds true and the performance of the wheel may be analysed by a study of the velocity diagrams at the entrance and the exit of the buckets or vanes. This analysis is indicated in Fig. 75.

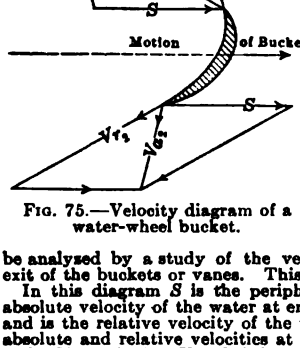

FIG. 75.—Velocity diagram of a water-wheel bucket.

In this diagram $S$ is the peripheral velocity of the bucket, $Va_1$ is the absolute velocity of the water at entrance, $Vr_1$ is the resultant of these two and is the relative velocity of the water at entrance. $Va_2$ and $Vr_2$ are the absolute and relative velocities at exit. It is the object of good design to make $Vr_2$ such that $Va_2$ shall be as small as practicable. But this can be so fixed for only one condition of speed and gate opening. It is this which makes it important to know in advance the conditions under which the wheel is to operate.

**683. Types of water-wheels.** Modern water-wheels may be classified either as reaction or impulse wheels. While the same fundamental theories hold for each, as pointed out in Par. **682**, the outward form and the method of utilising the water are radically different in the two types. The **reaction wheel** (turbine) utilizes in the main the pressure of the water and the reactive force on the curved buckets which tend to change its direction. An **impulse wheel** utilizes the velocity and impact of a jet of water directed against buckets on the rim of a wheel. The two types are primarily adapted to widely different conditions: the reaction wheels are best adapted to relatively low heads and large quantities of water; the impulse wheel to high heads and small quantities of water. In recent years reaction wheels have been used for all ranges of head up to 600 or 700 ft., where the units are large. But for heads upwards of 200 ft., with small flow, the impulse wheel of the Pelton type is the natural selection.

**684. The speed of turbines** for a given output and head is confined within quite narrow limits. As noted in Par. **682** there is for any given set of conditions a best speed. This for modern reaction wheels is such that the peripheral velocity is from 0.60 to 0.85 of the theoretical spouting velocity of the water due the head. The best speed may be, and is, varied by design, the recent tendency being toward the development of wheels with high relative velocity; this is easily overdone and is oftentimes secured at the expense of part-gate efficiencies. The best relative bucket velocity in the case of impulse wheels can be shown analytically to be 0.5 and this has been verified by actual tests. Characteristic curves for a modern reaction wheel are given in Figs. 76 to 78 inclusive.

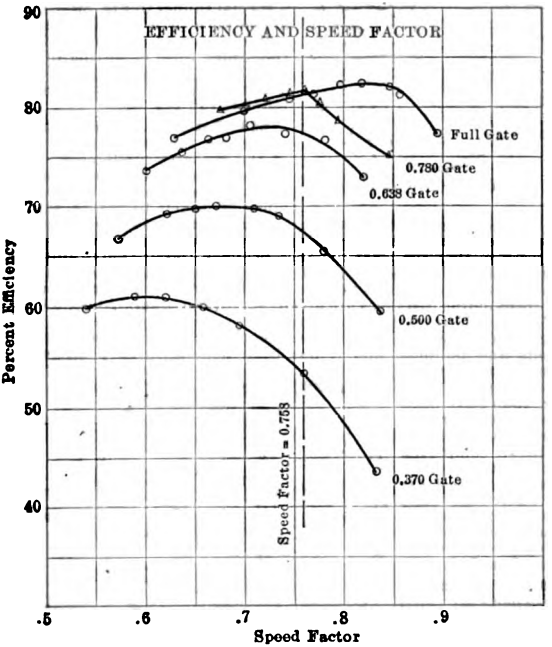

FIG. 78.—Characteristic curves—48-in. turbine.

**685. The efficiency** of modern water-wheels has been steadily improved by experiment and design until the makers can now guarantee test results of from 80 per cent. to 90 per cent. at the Holyoke Testing Flume (Par. **707**). To get the same result in place requires the best design of the setting and waterways. Many wheels which came up to specification in the Holyoke test have failed signally in place to show the power and efficiency of which they were capable. In most of these cases the fault was not in the wheel but in the setting. A wheel improperly installed is not given a fair chance. By carefully tracing the velocity through the penstocks, wheel case, discharge case and draft tube, using net areas throughout, it is possible to design settings which avoid high velocities and undue changes of velocities and direction, and results in place equal to the Holyoke test results may be expected. Efficiency curves for a modern reaction wheel are given in Fig. 78.

Digitized by Google

**685. Water velocity through guide chutes.** Mention has already been made of the importance of keeping the velocity of the water through headgates, canal and racks low. It also should be kept low, not over 3 ft. per sec., as it approaches the guide chutes of the runner itself. There is an exception to this in the case of single runners set in the so-called scroll case. In these, wheel makers are now requiring a velocity of about 15 per cent. of that due to the head acting on the wheel.

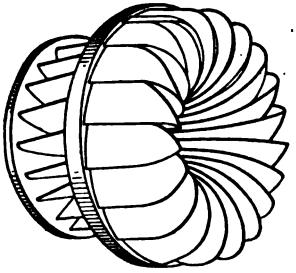

FIG. 79.—Cylinder gate runner.

**687. Mechanical details.** A cylinder-gate runner is shown in Fig. 79, and a special runner in Fig. 80. The general appearance of a vertical turbine with cylinder gate is shown in Fig. 81, with the usual form of setting in a concrete wheel pit. The same type of wheel with a horizontal setting in a steel flume is indicated in Fig. 82.

**688. Settings.** There must be equal chance for the water to feed to all parts of the guide circumference. When one or more pairs of wheels on the same shaft are set horizontally, extra care must be taken to insure that the last wheel in the line can draw its share of the water under as favorable conditions as the first wheel. A pair of centre-discharge wheels should be set in the case so that the clear distance between the discharge lips of the two runners shall be at least from 3 to 4 times the diameter of the runners. The greater distance should be used with higher heads; rough limits of heads and corresponding distances are given: 12 ft., 2.5 diam.; 18 ft., 3.0 diam.; 30 ft., 3.5 diam.; 50 ft., 4.0 diam.

Single, large, vertical units have recently received special attention from designers and builders, and it has been demonstrated possible to obtain efficiencies with them about 4 per cent. higher than have been obtained with horizontal settings of equal output. In comparing different settings it is important to know exactly where the head is measured; it is here assumed that the net effective head is taken. See also Par. 711.

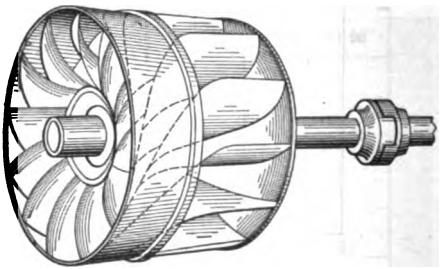

FIG. 80.—Special runner.

**689. Ratings.** Water-wheels are rated in horse-power, the rating given being usually the maximum output under the head stipulated. It is important to keep in mind three things: (*a*) that a horse-power is a smaller unit than the kilowatt (1 horse-power = 0.746 kw.); (*b*) that water-wheels driving generators must carry the normal load at from 0.75 to 0.80 gate in order to take care of overload on the generators; (*c*) when once under a given head the wheel is discharging its maximum quantity of water no further output can be wrung from it. The attempt to impose a heavier load can only result in reduced speed and output. Simplification would result if water-wheel ratings for hydro-electric plants were stated in kilowatts and generator ratings were stated in terms of the maximum output instead of normal rated output. This would remove the sources of confusion brought about by rating each half of an integral unit by a separate standard.

Digitized by Google

**690. Draft tubes** make it possible to set reaction wheels well above tail-water. This is a distinct and important advantage. It makes the wheels accessible for inspection and repair in spite of backwater conditions, and permits the use of horizontal wheels direct-connected to generator or shafting without sacrificing head. In a plant subject to severe backwater, if the machinery floor can be set 20 ft. above low tail-water elevation, draft tubes frequently save great expense in heavy construction and waterproofing of the power house.

A reaction wheel discharging freely into the air would be acted on by a head equal to the distance from headwater elevation to the elevation of the centre of the discharge orifices, minus such losses as occur. The pressure against the discharge is full atmospheric. If now we attach an air-tight pipe of suitable diameter to the runner case and conduct the water down from the wheel and discharge it under the surface of the water in the tailrace we have increased the head acting on the wheel, because now the pressure against the discharge from the wheel buckets is less than atmospheric by an amount corresponding to the vertical distance from buckets to tailrace, where the full atmospheric pressure acting on the water in the tailrace is holding up the column of water in the pipe or draft tube so-called (Fig. 84). A further gain is effected by gradually enlarging the cross-section of the draft tube. This reduces the velocity of discharge and some of the energy present as velocity is transformed into pressure within the draft tube. This increases the column held up by atmospheric pressure acting on the tailwater and correspondingly decreases the pressure against the discharge from the wheel. With good design this may amount to a foot of head. The flare should not be greater than approximately 1 in 10.

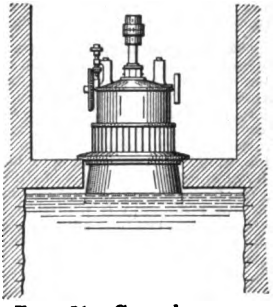

FIG. 81.—General arrangement of vertical turbine with cylinder gate.

The normal atmospheric pressure will support a column of water 34 ft. in height. Draft tubes are seldom used longer than 25 ft. There are

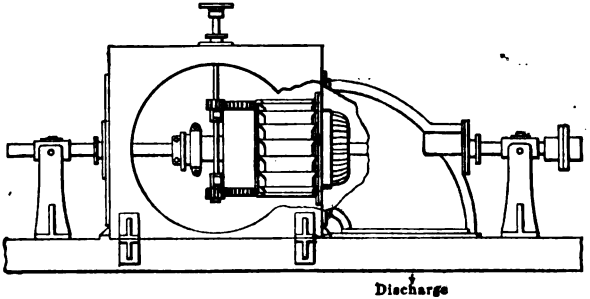

FIG. 82.—Cylinder gate turbine, horizontal type in steel flume.

structural limitations, inevitable losses and some leakage of air which makes it difficult to maintain to any greater height an unbroken column of solid water, essential to the success of the tube. It has been noted that the pressure within the draft tube is less than atmospheric. This necessitates an air-tight design suited to withstand collapsing pressure.

The velocity through the upper portion of the draft tube is necessarily high. For this reason, the interior surface should be smooth to minimise

Digitized by Google

friction and eddy losses; and in the case of horizontal wheels the obstruction caused by the shaft should be made as slight as possible. If draft tubes are set on an angle it should never be more than 45 deg. from the vertical. The elevation of the outlet should be fixed so that the draft tube shall be sealed during lowest tailwater conditions. The velocity of discharge from the tube should in general be a little greater than that of the water into which it discharges, but ordinarily not more than 3.5 or 4 ft. per sec. at full discharge.

**691. The tailrace** should be designed to carry the water away with a minimum sacrifice of head. It should therefore receive the same care in design and construction as the feeding canal.

**692. In selecting the type of wheel** to be installed in any power plant the natural conditions of head and flow, with their variations, and the power demand on the plant must be clearly and definitely understood. Stock wheels can be purchased which fit a wide range of conditions; special wheels may be designed to fit a far wider range. The following points should be covered in any wheel selection: (*a*) head, and its variation; (*b*) flow, and its variation; (*c*) speed, and the importance of close regulation; (*d*) power demand, and its variation. These may best be studied in connection with the characteristic curves of different types of turbines; it is in fact the only way of making an intelligent selection from stock designs. The fluctuation in power demand is probably the most troublesome point and the wheel which shows the best efficiency over the desired range may be readily picked out from a comparison of the curves. In the same way the effect of the variations of head on each type of wheel may be seen and allowance made in the choice. A set of common characteristic curves are shown in Figs. 76 to 78; these are drawn from Holyoke test results, reduced to the head under which the wheel is to operate.

Three examples are given below to illustrate three typical but variant requirements which water-wheels have met successfully. The number of units should be based upon the fluctuations in stream flow and power demand; but each unit should be ready to take care of momentary fluctuations.

(1) Ground-wood pulp mill. Here the wheels are run at full gate as long as there is water to run them. High speed is important, but moderate variations in head are of small concern.

(2) Textile mill. There is only moderate variation in load during working hours. Uniform speed is vital; therefore wheels which hold their efficiency for constant speed under variations of head are desired.

(3) Hydroelectric plant carrying a railway and lighting load. Here fluctuations in power demand are extreme and close regulation is essential. Such a plant frequently requires a specially designed runner; the requirements are obvious.

**693. Speed regulation.** The control of **reaction wheels** is effected by governors which act directly on the wheel gates. There are two general types of governors, mechanical and hydraulic. Either to be most effective should be of the relay type in which* "the energy is transmitted from a source independent—as to quantity—of the centrifugal governor balls but controlled by them in its application." In all cases in which the fluctuations in load may be large and sudden some form of relief must be provided. For open canals the spillway already described for getting rid of débris will answer. For long penstock lines standpipes or relief valves or both should be provided and careful study as needed to ensure the best results.

**Impulse wheels** may be governed by deflecting the stream away from the buckets or by throttling the stream. The throttling may be accomplished in the case of a multiple orifice nozzle by closing some of the orifices. The usual nozzle is known as the Doble needle nozzle. It is usually the case in impulse wheel installations that the head is great and the velocity of the water high. For this reason the inertia of the column of water contained in the penstock is such as to prohibit, on the grounds of safety, governing by throttling alone. In such cases the first action of the governor is to deflect the stream, the second and slower action is to throttle the flow. This combined control is the most economical of water.

* Mead, D. W., "Water Power Engineering;" New York, McGraw-Hill Book Co., Inc., 1908.

Digitized by Google

**694. Governors** have been developed and improved rapidly in recent years. The increasing demand for close regulation of power plants has stimulated this improvement until now there is a new type fitted to every new requirement. In general it can be said that for small units and for cases of which the textile plant is representative the mechanical governor is admirably suited. For large units such as are becoming common in hydroelectric practice the hydraulic governor is better fitted to develop the great force necessary to operate the turbine gates. According to Mead* governor specifications should call for a guarantee of the following: (*a*) sensitiveness or per cent. load change which will actuate the governor; (*b*) power which the governor can develop and force which it can exert to move the gates; (*c*) rapidity with which it will move the gates; (*d*) anti-racing qualities, such as number of gate movements required to adjust for a given load change; (*e*) general requirements of material, strength, durability, etc. The hydraulic engineer can simplify governing to a marked degree by good design of the penstocks, draft tubes, etc.

**695. Operation.** The cost of operating a hydroelectric plant is from 10 to 15 per cent. of the first cost.

**696. Cost data.** A sub-division of costs for a typical case is as follows:

| Item | Per kw. year |
|---|---|
| Interest 6 per cent. on $124.5 (Items 1–5, Par. 680) | $7.47 |
| Depreciation 10 per cent. on 21.4 (Item 5, Par. 680) | 2.14 |
| 2 per cent. on 26.5 (Items 2 and 4, Par. 680) | 0.53 |
| 1 per cent. on 52.6 (Item 3, Par. 680) | 0.53 |
| Ordinary repairs and maintenance $2½ per kw. year | 2.67 |
| Administration 1.00 per kw. year | 1.00 |
| Taxes 2 per cent. on 75.0 (60 per cent. of total cost) | 1.50 |
| Insurance ½ of 1 per cent. on 33.4 (Items 4 and 5, Par. 680) | 0.17 |
| | $16.01 |

Note that interest at 6 per cent. and depreciation are two-thirds of the total. Steam relay to supplement dry-weather flow will add 25 per cent. to operating cost *without coal*, if charged against the water power.

## PLANT DESIGN

**697. General ensemble.** The location and relative position of the dam, head-works, power house, tailrace, and all other necessary structures must be governed to a large extent by the topography and the geological conditions at the site. The choice between various possible schemes will be based in the main upon the relative cost considered in connection with the efficiency of the proposed plant as an energy producer, or as an income producer. The height to which the dam may be built is usually limited by the extent of flowage damage. In a hydroelectric plant pondage may have great value, making fully warranted the purchase of extensive flowage rights. The spillway section of the dam should be designed to pass safely the maximum amount of water that can be expected. Likewise the abutments and other shore structures must be built to withstand successfully the greatest freshet conceivable on the river. In this connection it is important to realise that under extraordinary flood conditions the channel above and below the dam, and not the dam itself, may frequently control the height to which the water rises. This is especially likely to be the case when the dam is built at the head of rocky tortuous rapids or in a bend of the river.

The intake should draw water from the stream with as little change in direction as feasible and must be protected by some form of boom which shall direct ice and floating débris away from the head-gates and over the dam, or through a waste channel designed for that purpose. Additional head may be obtained over that at the dam itself by carrying the water downstream in canals or penstocks. The advisability of such procedure is determined by a study of the fixed charges on the structure and the value of the increased energy so obtained.

The whole system of waterways from head-gates through the canal or penstock, racks, wheelpit and tailrace to the river should be designed to

* Mead, D. W., "Water Power Engineering;" New York, McGraw-Hill Book Co., Inc., 1908; Chap. XVIII, p. 467.

Digitized by Google

keep the velocities low enough to avoid excessive loss of head. Fluctuations in velocity are bad, and if unavoidable the changes should be made gradually. It is better to gradually speed the water up from say 1 ft. per sec. at the head-gates to not more than 3 ft. per sec. at the wheel gates, in the case of the ordinary vertical or horizontal setting; the exception in the

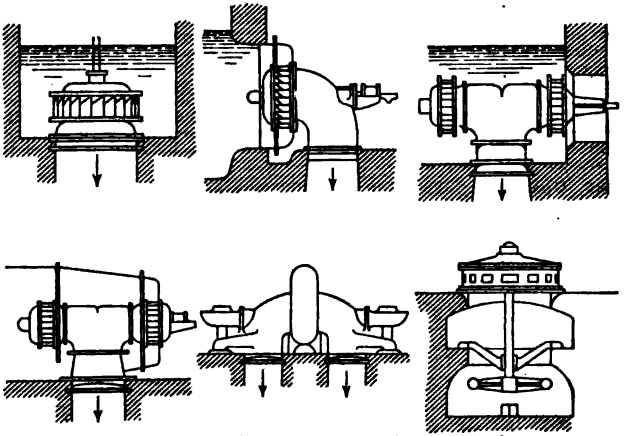

FIG. 83.—Miscellaneous settings of water-wheels.

case of scroll case settings has been noted in Par. **686**. Where more than one wheel is mounted on a shaft it is important to provide for equal distribution of the water among the units, and to provide against interference in the draft chest as mentioned in Par. **688**. The velocity at the top of the draft tube is necessarily high and should be gradually reduced by enlarging the cross-section of the tube until it is discharged at about 3 ft. per sec.

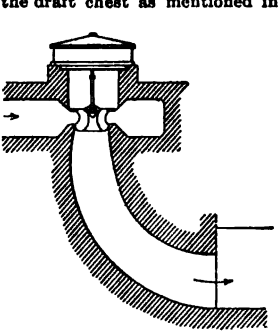

FIG. 84.—Single vertical turbine in a spiral flume direct connected to a vertical electric generator.

**698. Typical settings** of water wheels are shown in Fig. 83. A modern form of setting known as the spiral or scroll casing is illustrated in Fig. 84, which shows a longitudinal vertical cross-section. The latter type of setting is employed at the Keokuk plant of the Mississippi River Power Co.

**699. The economical development** of a water-power proposition must depend upon the available power in the river, the market, and the degree to which auxiliary power is to be employed. Two things must be determined as exactly as possible: (*a*) the hydrograph of the river (Par. **658**); (*b*) the load curve.

A thorough and exhaustive study of all run-off data should be made where these are available; otherwise study must be made by comparison with similar drainage areas by means of rainfall data. Existing and possible storage should receive careful attention. It should be remembered that on streams with incomplete storage *averages are dangerous*, leading to overdevelopment. Two or 3 days of flood discharge in a month

Digitized by Google

much above the capacity of any possible equipment can raise the monthly average to give a totally erroneous impression of the kilowatt hours available. For this reason, daily records of flow should be used in preference to monthly records, since the daily records bring out the maximum and minimum flows and the final estimate can be much nearer the truth.

The probable load curve is of prime importance, and taken together with the available pondage it will determine the number and size of units to be installed to give flexibility and economy in operating.

**700. Auxiliary power.** If a relay station, steam, gas or oil, be used, it should be placed as near the market or sources of fuel as economic conditions warrant. Its capacity must be determined by the daily and yearly hydrograph and the load curve. So many combinations of conditions of pondage, storage and load occur that every case must have special and detailed study. There are very few developments where a relay station owned either by the seller or the buyer of hydroelectric energy is not almost essential.

**701. Choice of units.** With varying load, efficiency requires two or more units so that during the hours of minimum demand the machine or machines on the line can carry the load at good efficiency. Then as the load comes on additional machines are cut in as needed.

**702. Provisions for handling floods** include: (*a*) **flashboards**; (*b*) **Tainter gates**; (*c*) **sluice gates.** It has been noted that the height to which a power dam can be built is usually limited by the extent of the flowage permissible (Par. **697**). This necessarily applies to the high-water stages which may be expected every year, and settlements for the necessary rights are usually made once for all. During most of the months in each year increased pondage or head, or both, can advantageously be procured by raising the dam without creating greater flowage than occurs during high water from the dam at its permanent elevation. This is accomplished in a number of ways, but most commonly on power dams by the use of flashboards which are designed to bend over or go off during floods. In this way provision is made for handling floods at the moderate cost of replacing the flashboards.

In order to provide for the occasional summer freshet and to give greater discharging capacity in cases of great freshets **flood gates** are incorporated in many modern dams. When warned of a freshet, probably of short duration, it is frequently possible by opening the gates in the dam to pass the extra water without straining or losing the flashboards. Flashboards are ordinarily held in place by either wrought-iron pins which will bend over, or light wooden figure-fours which will break when the water rises too high. The development of water power on navigable streams also leads to the use of Tainter gates, Chanoine wickets, Bear traps and other forms of movable dams ordinarily suited to their purpose, but which in northern rivers carrying much ice must be designed with great care.

**703. Log sluices and fish ladders** are necessary appendages to most power dams. A log sluice is an inclined chute on the downstream side of the dam with a gate at the crest which is opened whenever a log drive must be run past the dam. These are usually required by law where log driving has ever existed on the river. Fishways are required by federal law on most rivers and must be kept open during certain portions of the year. There are various forms, two of which are mentioned. One is constructed to form a flight of pools, the water spilling into each successively. The other is a chute set at a moderately flat slope with baffles built alternately from the right and left sides, about three-quarters of the way across.

**704. Buildings and foundations.** The conditions controlling plant design are discussed in detail in Par. **697**, **700** and **701**. Foundations are usually subject to water pressures due to head or backwater or variations from drought to flood conditions. These conditions usually require foundations much in excess of ordinary building requirements.

The size, height and arrangement of buildings usually follow these hydraulic conditions and the type of unit selected.

**705. Summary of unit costs.** Unit costs common to most water-power developments with some idea of the range of prices which depends upon the amount of each contract, distance from markets, difficulties of handling, etc., are:

Digitized by Google

## TESTING

**706. Water-wheel testing** has played a vital part in the improvements which have been accomplished in the design and construction of turbines. Every water-wheel should be tested if possible before it is installed. That a similar wheel of the same make, diameter and pattern has been tested and shown satisfactory results is no guarantee that a wheel which has not been tested will give similar results. The expense of the test should never be allowed to militate against it, for a gain of only 1 per cent. in efficiency will pay for the test in a relatively short time. Specifications and guarantee requirements should be drawn with care and include where feasible provision for final acceptance tests in place, in addition to the preliminary tests at the Holyoke Testing Flume. In addition to finding out whether the wheel has met the specification requirements, the tests furnish data by means of which the use of the wheel as a water meter is possible (Par. **663**).

**707. The Holyoke Testing Flume** furnishes the only place in this country where systematic testing is carried on. The maximum head is 17 ft. and the maximum discharge possible is between 250 and 300 cu. ft. per sec., at which discharge the head is reduced nearly one-third. In spite of these limitations the tests are invaluable to the water-power engineer and form a common basis of comparison for designers.

**708. The quantities to be measured** in a water-wheel test are speed, head, discharge and power output. At the Holyoke flume these are observed by a revolution counter, head and tail water gages, weir and Prony brake, respectively. Various gate openings are selected and for each opening the wheel is run at many speeds in order to determine the most efficient speed for each gate.

**709. For making the final acceptance test** of water wheels a test in place is becoming more frequent. Such a test furnishes direct evidence of the performance of the wheels under service conditions.

**710. The general problem** is that of any test of power machinery; namely, to measure the input and the output. To measure the input requires the measurement of the head and the quantity of water used by the unit under test.

**711. The points of measurement of the head** should be selected to show the net head actually acting on the wheel. Friction losses in canal or penstock and tailrace are not properly charged against the performance of the turbines, however much they may affect the overall efficiency of the plant. The point therefore at which to measure the headwater is just before the water is drawn to the guide chutes, and the tail-water should be observed at the nearest feasible point to the discharge of the draft tube. In open flume settings the head water is observed in the flume. In the ordinary pressure-case setting a gage should be tapped into the side of the penstock (Par. **640**, *piezometers*) just clear of the case in order to avoid disturbances due to eddies and uneven flow in the case. In a scroll-case setting, the scroll, like the draft tube, must be considered an integral part of the wheel and the head should be measured between the entrance to one and the discharge of the other.

**712. Measurement of the quantity of water used** presents some difficulties unless special provision was made in the design of the plant. It has been usual practice to install a weir in the tailrace. Unless the conditions are exceptional the results are subject to serious but undeterminable error due to the relatively high velocity of approach to the weir (Par. **609** *et seq.*). The attempt is made by building the crest high enough from the bottom to cut down the velocity, the head acting on the wheel is thereby reduced and

Digitized by Google

at once the actual service conditions are only approximated and the peculiar value of the test in place is partially vitiated. It is difficult to make the conditions of the channel of approach to the weir suitable for good measurements and the expense of installation is relatively great. Whatever method of measurement is used, there should be an agreement in advance by the buyer and seller of the wheels to accept the results. Where conditions for their use are right, rod floats (Par. **643**) afford an excellent means for measuring the flow either in the headrace or tailrace.

The easiest measurements to make properly are probably those with a current meter (Par. **662**). The expense is slight and in the hands of careful and experienced operators simultaneous measurements in head race and tailrace will give excellent results without interfering in any way with the normal service conditions of operation. Suitable measuring stations may be easily included in the original design of the plant at little or no extra expense.

For relatively small units fed by penstocks, the most accurate measurement without question can be made by a venturi meter (Par. **686**) incorporated in the penstock when the plant is installed. When properly rated it has the great advantage of giving a continuous record of flow.

**713. For measuring the output** two general methods are available for a hydroelectric station. They are (1) to measure the energy generated electrically, or (2) with some form of absorption dynamometer. The electrical measurement requires that the driven dynamo shall have been carefully tested and the efficiency determined for all loads. Electrical measurements can be made with great accuracy but the determination of the turbine output by this means is somewhat indirect. With the development of the **Alden dynamometer** direct and accurate measurement is possible. This apparatus is described as follows by Prof. C. M. Allen:

"It is a form of Prony brake, and usually consists of several smooth circular revolvable cast-iron discs keyed to the shaft which transmits the power; a non-revolvable housing having its bearings upon the hubs of the revolving discs; and a pair of thin copper plates in contact with each cast-iron disc, the plates being integral with the housing. Through a system of piping, water under pressure is circulated through chambers between the units, each consisting of a disc and its copper plates, and between the outer plate at either end and the wall of the housing. The water pressure is regulated by hand or by an automatic valve. Another system of piping circulates oil for lubricating the surface of the copper plates next to the revolving discs."

**714. Advantages of the test in place.** The test in place, if made complete enough to cover all gate openings under normal conditions of head at the plant, will serve two purposes: it will tell whether the wheels tested are up to specification; and it will provide a means of measuring the daily or hourly amount of water drawn by the plant so long as the wheels are kept clean and in good repair, and the operating conditions are essentially those obtaining during the test. These records if carefully kept become of great value to the owner and operator of the plant.

## ELECTRICAL EQUIPMENT OF POWER PLANTS

### BY GEORGE I. RHODES

*Consulting Engineer, White, Weld and Co., Member, American Institute of Electrical Engineers*

### ELECTRIC GENERATORS

**715. Types of generators** are covered in Sec. 7 and Sec. 8.

**716. Generator characteristics required** for a given power plant are largely determined by the size, overload capacity, speed, speed variations, and possibilities of over speed of the prime mover; the size of the plant, the number of units, the load factor, fluctuations and power-factor of the load; the voltage and type of the distribution system.

**717. Sizes of generators.** The ratio between the adjacent sizes of generators varies from 1.25 to 1.50. The size limitations seem to have been reached only for direct-current generation, where 2,700 kw. is the largest obtained commercially. Engine-driven alternators are in operation which will carry from 8,000 to 10,000 kv-a. continuously without overheating. Water-

Digitized by Google

wheel alternators are built up to 20,000 kv-a. and there is little doubt that larger sizes can be built if required. Steam-turbo-driven alternators are being built up to 30,000 kv-a.

**718. Overload capacity** in generators is necessary only when the prime mover has ability to deliver loads greater than rating, or in special cases where it is desirable to install a generator smaller than the maximum output of the prime mover. Gas engines which will stop when their rated capacity is much exceeded, require generators which will reach their maximum safe temperature when continuously operated at rated load. This same condition is required of steam turbines when rated at the maximum capacity, and by water-wheels except in very unusual circumstances. Steam engines which are rated at their most economical load, or steam turbines having overload valves, require generators with considerable overload capacity. Generators of the first class are usually designed to carry their rated load continuously with a temperature rise of about 50 deg. Cent. Generators of the second class are designed to carry rated loads continuously with 40 deg. Cent. temperature rise, and 25 per cent. overload with a 55 deg. rise. It is doubtful if this latter temperature is safe except for temporary operation.

**719. Speeds** of standard designs range from 75 r.p.m. upward, the ratios between adjacent speeds being from 1.1 to 1.2. Low speeds are confined to large machines. Several speeds for the same size are usually available, particularly in small and moderate sizes. The speed of direct-current machinery is limited by commutation. High-speed direct-current generators, even of relatively small size, are not recommended. The speed of alternating-current generators is controlled by frequency and by number of poles. At the high speeds, ventilation becomes one of the principal problems, but the manufacturers have solved it to such an extent that machines are offered in sizes up to 5,000 kv-a. at 3,600 r.p.m. and up to 30,000 kv-a. at 1,500 r.p.m.

High-speed generators deliver short-circuit currents of enormous instantaneous value, even though the sustained short-circuit currents are limited. This characteristic is of greatest importance in large systems, particularly in reference to switching methods (Par. **799**).

**720. Speed variations or fluctuations in the driving torque** have a tendency to accentuate the difficulties of commutation. In alternating-current machines the speed variations are of great importance to parallel operation, particularly when the speed is low and the number of poles is large. The driving impulse in gas engines and low-speed steam engines being non-uniform, flywheels of large moment of inertia are required to keep down the speed fluctuations so that satisfactory parallel operation may be obtained. It is usually necessary to have alternators for this service designed with large armature reaction and reactance, so that the angular variations will produce a minimum of surging in the electrical circuits. With gas engines it is necessary to use short-circuited pole-face windings.

**721. Runaway speeds.** In engines and turbines it is easily possible to provide emergency governors so that generators need be specified to stand only about 30 per cent. overspeed. In water-wheel units, however, the difficulty in caring for the inertia of the water in long pipe lines makes it necessary to have generators safe at 90 per cent. to 100 per cent. over-speed.

**722. Inherent regulation.** In very small plants good regulation is to be sought for, particularly on account of the lack of skilled attendance, and also on account of the large number of other uncontrollable influences affecting the uniformity of voltage. In the larger plants the question of regulation is of less importance because of better attendance and the feasibility of automatic regulating devices.

In very large plants the importance of keeping down short-circuit currents, both instantaneous and sustained, looms up in such large proportions that regulation is completely neglected except as may be necessary to secure proper conditions of parallel operation. In these large plants it is usual to go to considerable expense to secure automatic regulation of voltage allowing generators of exceedingly low inherent regulation. Induction generators and current-limiting reactances (Sec. 6), are also used in some large plants to limit short-circuit currents.

Digitized by Google

**723. The number of units** has relatively small influence except as affecting parallel operation, the conditions of which are more exacting in a plant of many units. (Also see Par. **724**.)

**724. The load factor**, or the form of the load curve has particular influence in determining the number of units to be installed and the overload capacities of the same. With a steady load for 10 hr. per day, generators should be installed to carry the load with one unit shut-down, without exceeding the overload capacity. With large short peaks for a few months in the year, and much smaller loads during the other months, the peaks can safely be carried at overloads even in excess of 25 per cent. for which generators are frequently specified.

**725. Load fluctuations.** If the load is widely fluctuating, such as on electric railways of few cars, the commutation limit of direct-current machines determines the size to be installed. Interpole generators with ability to commutate loads far above the usual rating are frequently used so that the average load may approach the heating limit. In alternating-current machines this question is of less importance, as they are stable at very considerable momentary overloads. In single-phase railway systems where violent short-circuits are frequent the windings need to be specially braced. Fluctuating loads will cause considerable voltage variation and may determine the requirements of regulation, particularly in small and medium size plants. Compounding is almost invariably resorted to in direct-current plants and sometimes in small alternating-current plants; even then there is considerable variation in voltage, especially on rapidly varying loads.

**726. The power-factor** determines not only the kilovolt-ampere rating of the generators to be installed, but also the size and resistance of the field windings. Machines required to carry lagging loads need larger fields than machines to carry leading loads of the same magnitude. Generators are usually supplied with field windings suitable to care for full inductive loads at 80 per cent. power-factor. This is usually sufficient to take care of any condition which may be expected.

**727. The voltage.** Direct-current machines are available at 125 volts, 250 volts, two-wire and three-wire, and 600 volts, with 1,200 volts as a possibility, alternating-current machines at the above voltages and in addition 2,300 volts, 2,300/4,000 volts, four-wire, three-phase, 6,600 volts, 11,000 volts and 13,200 volts. Higher than 2,300 volts, without the use of compensators or transformers, is not recommended in small high-speed machines. 11,000 volts and above in turbo-generators, except of largest size, should be avoided, but is entirely safe in slow-speed machines. Other voltages are used at times but the machines are special. Occasionally it is desirable to use generators connected in delta at 2,300 or 6,600 volts but insulated for 4,000 or 11,000 volts, making it possible later to increase the voltage of the system. High-voltage machines are usually star connected, because of the possibility of larger conductors and more rigid windings.

**728. Foundations** for electric generators are usually parts of those of the prime movers. The type and form is largely dictated by the requirements of the prime mover. It is becoming the practice to support turbo-generators on skeleton foundations and even directly on the floor with a basement underneath. For the cost and detailed design see Sec. 10.

**729. The erection of generators** covers a considerable range of work depending upon the method of shipment. Small machines are shipped completely assembled and the erection consists merely of placing in position and leveling. With larger units the facilities for transportation and hauling limit the sizes for separate parts and in extreme cases the machines are shipped almost completely dismantled, requiring the most careful work in erecting them and preparing them for preliminary operation by drying and voltage tests.

**730. Preliminary operation** requires a determination of the polarity or phases, before actual connection to the lines, as well as careful watching and testing during operation necessary to determine whether or not the machine is perfect and ready for regular and continuous service. Phases as marked in the factory should not be depended upon unless testing is impossible.

Digitized by Google

Phases and synchronising equipment may be checked by connecting to a spare machine and bus, bringing up to speed with the spare machine and synchronizing by the use of the apparatus on the spare machine. If no spares are available, lamps, alone or with shunt transformers, connected across the open switch may be used. Simultaneous dark lamps indicate correct phases; when lamps do not darken and brighten together crossed phases are indicated.

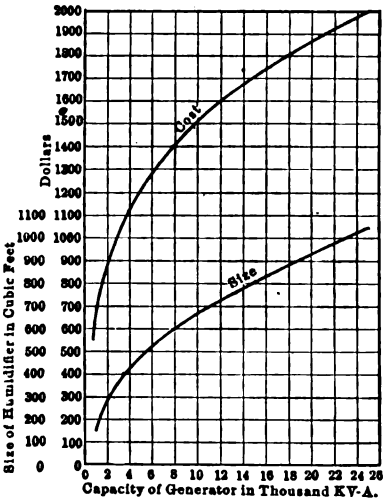

FIG. 85.—Size and cost of humidifiers (*G.E. Rev.*, Sept., 1913, p. 634).

**731. The volume of air required for cooling** is generally about 5 cu. ft. per min. per kv-a. of generator capacity.

**732. Cleaning the air** is a matter of great importance but frequently neglected. Dirt which clogs up the air passages and coats the cooling surfaces prevents proper cooling and shortens the life of the machine. Reasonable cleanness may be secured by having the intake above the roof, thus keeping out all but the finest dust. If the air must be taken from near the ground, it should be filtered by passing at low velocity through one or more thicknesses of cheese cloth or Canton flannel. Complete cleaning requires large areas, amounting to about 1 sq. ft. per kw. of generator capacity. Means must be provided for the ready cleaning

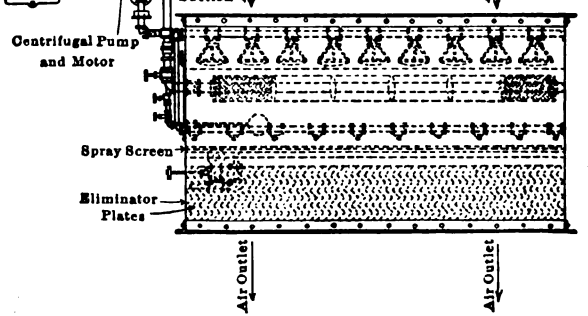

FIG. 86.—Air washer, Spray Eng. Co.

Digitized by Google

and replacement of screens. Water screens or humidifiers are coming into favor, the air being passed through falling water which takes out the dust, and the nfreed from mist by baffles (Fig. 86). This method has the added advantage of cooling the air several degrees. The value of this may be seen in Fig. 87.

**733. The cost of erection** and preliminary operation of generators ranges between wide limits depending upon local conditions. Smaller machines which are shipped assembled may cost for erection and preparation for regular service, in reasonably equipped stations, from 4 per cent. to 5 per cent. of the cost of the machine at the factory. If the machine is shipped dismantled, the cost of erection will be about 1 per cent. to 2 per cent. higher. The cost of erecting large machines is from 4 per cent. to 5 per cent., and in a few cases where conditions allow shipment assembled, about 1 per cent. can be saved. An average cost, for machines from 500 kw. to 6,000 kw., can be obtained from the formula $C = \$400 + \$0.32$ kw., where $C$ is expressed in dollars. Freight and haulage is dependent absolutely on location and local conditions, and may vary from 1 per cent. to 15 per cent. of the cost of the machine.

**734. Ventilation.** The continued success of ventilation methods has a most important influence in determining the life of the insulation. The requirements call for a plentiful supply of cool air free from dust, oil and excessive moisture. Except in turbo-generators, no special means are taken to fulfill these conditions other than those provided in the machine. In high-speed turbo-generators, however, large volumes of air at enormous speeds are passed through the windings, and the utmost pains should be taken to maintain the best possible conditions. In most stations it is customary to take the cooling air directly from, and discharge it into the turbine room, but in cases where the room cannot be well ventilated, this arrangement may overheat the room and the machines. In some stations it has been found possible greatly to increase the capacity of the generators by installing specially designed vanes on the rotors, thus passing much larger volumes of air. With a machine thus ventilated, the coils quickly become dirty and much care has to be exercised to keep out the oil that permeates the atmosphere. In the larger stations it has been found important to install ventilating ducts taking cool air directly from outside the building.

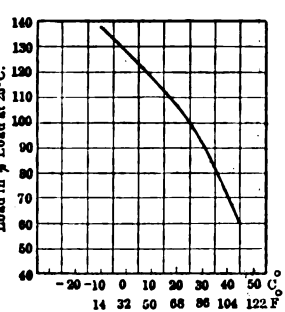

FIG. 87.—Safe load and temperature of cooling air (*G. E. Rev.*, Sept., 1913, p. 633).

The ducts should be of liberal size to keep down air velocities to about 1,000 ft. per min. Dampers should be provided to enable shutting off the air supply in case of burn-outs. Ventilation by separately driven blowers is being used and is strongly recommended by some engineers.

**735. The cost of ventilating ducts** arranged for cleaning the air should not be more than 25 cents per kw. of generator capacity.

**736. The operating temperature,** combined with the kind of insulation, determines absolutely whether or not the machine is overloaded. Temperatures are difficult of measurement, particularly in respect to finding the hottest parts. It is the maximum temperatures which are of importance, and it is probable that these are never found in tests. Resistance temperature tests are difficult to make, and in large machines take considerable time after shut-down; such tests give only average copper temperatures, which are certainly less than the maximum. Ordinary thermometer tests give the temperature of the outside of the insulation, and by means of refinements it is possible that maximum temperatures can be measured to within 10 deg. to 20 deg. Cent., but this method is not recommended. Resistance thermometers and thermo-couples, inserted between the coils and the iron, have been used with considerable success. The actual indicator may be

Digitized by Google

located anywhere convenient, even on the switchboard, where continuous record of the temperature may be kept. This method gives more consistent and precise results than the others and probably shows more nearly the maximum temperatures.* Indicating electric thermometers, several for each machine, can be installed for $100 to $200 per machine.

**737. Safe temperatures of insulation** are given by C. P. Steinmetz and B. G. Lamme in the February, 1913, *Proceedings* of the A. I. E. E. as 90 deg. Cent. for fibrous insulation such as is commonly used, and 125 deg. Cent. for mica and other fire-resisting materials. These temperatures are the measurable temperatures rather than the absolute maximum that may be expected in local spots. H. G. Stott recommends 20 deg. lower temperatures, especially on high voltage work.

## EXCITATION

**738. Excitation equipment** should be designed with a view to the maximum possible **continuity of service.** Simplicity, ruggedness, "fool-proofness" and reserve apparatus are important requirements. The methods in use for securing these results are greatly varied and much difference of opinion exists as to the best method. Each plant must be considered as a separate problem.

**739. Exciters directly connected to the main generators** were the earliest form in use. They are now seldom used in steam or gas engine plants, but are used in some of the largest and most recent hydroelectric stations with satisfactory results. Each exciter is frequently made large enough to handle two generators, in emergencies. The chief arguments in favor of this method are simplicity, high efficiency and the absence of large field rheostats. The most important objections are the possible crippling of a large unit due to trouble with its exciter, and the fact that voltage fluctuations in per cent. are twice as great as the speed fluctuations.

**740. Exciters driven by separate prime movers are necessary** in all stations except those above mentioned (Par. 739). They may be obtained for service with any kind of prime mover. On account of their small size the efficiency of the unit is very poor, this constituting the chief objection to their use. Where steam at atmospheric pressure is necessary for feed-water heating, the inefficiency is of no importance. Their use is determined principally by questions of convenience and economy, it being absolutely necessary to install them for starting purposes.

**741. Motor-driven exciters** are in use in almost all stations. They are cheap, economical, efficient and reliable, but cannot be used for the complete equipment. They should not be driven by synchronous motors, because short-circuits on the outside system not in themselves sufficient to cause a shut-down of the station, are likely to throw the motors out of step, thus shutting down the plant. Induction motors are almost invariably used. A well-balanced exciter plant consists of units driven both by motors and by prime movers. In some cases, motor-driven units are considered as auxiliary to the prime-mover units, and in other cases the motor-driven plant is considered of first importance; the first plan is probably most in favor.

**742. The importance of continuous excitation** points strongly to **storage batteries** which are frequently installed of sufficient capacity to excite the entire plant for an hour. Danger of a shut-down of the entire plant by failure of the exciters is not considered great enough in all cases to warrant the great expense of a battery. When used, it may either be floated on the excitation busses, or allowed to stand by fully charged.

**743. A new method of securing continuous service** is being introduced with great promise. The exciter generator is arranged to be driven both by motor and prime mover. The motor is provided with a relay which shuts it down if the voltage becomes low. The governor is arranged practically to shut off the steam at normal speed, but after cutting off the motor, the prime mover continues to drive the unit at but slightly reduced speed.

Digitized by Google

**744. The size of the exciter plant** depends upon the size of the power plant and the types of generators used. Small, low-speed generators require up to 3 per cent. of their capacity for excitation. Large, high-speed turbo-alternators may require as little as 0.75 per cent. The exact requirements may be obtained from the manufacturer. The total capacity should be ample to carry the whole excitation load with the spare apparatus out of commission. The amount of spare apparatus required is not very definite; practice ranges all the way from depending on the overload capacity to having two to three times the total capacity required.

**745. The number and relative size of the exciter units** should be chosen for the greatest simplicity and the required flexibility. The minimum size of any unit is in general dictated by the requirements of the largest generator. It is doubtful if the largest exciter should be large enough to excite the entire plant. Except in very large plants a size sufficient for half the equipment, with a total of three units, will give very satisfactory results.

**746. The exciter voltages** in common use are 125 volts for all except the very largest plants where 250 volts are used. The generators are usually flat compounded. With standard exciters it is possible to run at not more than 15 per cent. over standard voltage, which is quite sufficient to take care of the excitation of ordinary alternators at full-load. Where overload capacities are to be used, it is frequently desirable to raise the excitation voltage as much as 25 per cent. during the peaks. Exciters can usually be arranged for this voltage with very little deviation from standard design.

**747. The cost of exciter sets installed,** ready to run, exclusive of wiring, piping, etc., correct to plus or minus 10 per cent., (covering ordinary differences in speed and other commercial differences in design), may be expressed as follows:

| | |
|---|---|
| High-speed compound-engine drive, | $1,000 plus $35 per kw. |
| High-speed simple-engine drive, | $750 plus $26 per kw. |
| Steam-turbine drive, | $425 plus $31 per kw. |
| Induction–motor drive, | $625 plus $15 per kw. |

The cost of exciters attached to the shafts of the main generators can best be expressed as a percentage of the cost of these generators; this will vary from 3 per cent. to 5 per cent., depending somewhat on the speed.

**748. Exciter wiring systems** are in use covering practically all the direct-current types of switchboards. On account of the low voltage no complications need be entered into except as may be necessary to make available the various sources of excitation. Occasionally a double exciter bus is desirable, but in most cases it adds complications without any adequate gain to the service. Alternating-current wiring for motor-driven exciters should be worked out on the basis of the exciters being most important feeders, unless, however, the presence of a storage battery makes this treatment unnecessary. In stations above 2,300 volts, it is recommended to use transformers in connection with the exciter motors, as small machines wound for high voltage are not of sufficient reliability.

**749. Excitation switching appliances.** The current must not be broken without at the same time short-circuiting the field windings, otherwise punctured insulation will result. This requirement calls for special field-discharge switches. It also limits the use of circuit-breakers to those operating on reverse current, thus serving to cut out damaged exciters. Fuses of very large overload capacity, which will blow only during most severe trouble, are used for the protection of the exciters.

**750. Field rheostats** for small generators are usually mounted on the back of the switchboard, but for large machines some more conveneint location involving remote control is necessary. Electrically controlled rheostats are frequently necessary in large stations and are operated either by solenoid and ratchets or by motor; the latter is necessary where the field current exceeds 300 amp.

## VOLTAGE CONTROL

**751. Hand regulation.** Voltage is controlled in all systems by hand regulation, whether or not there are automatic means. Hand regulation alone is suitable only where the load is steady and the generators inherently regulate well.

Digitized by Google

**752. Automatic regulation** may be secured by two methods; first, the automatic adjustment of the field resistance by motors or solenoids controlled by a relay; second, the alternate short-circuiting and insertion of resistance in the field circuits. The first method is used in the **Thury regulator** the second method in the **Tirrill regulator.** The first method makes the adjustment more or less gradually; the second changes the resistance much more than necessary, alternately one way and then the other, while the time lag of the field windings produces a practically steady voltage of a value depending upon the proportionate time the resistance is in and out of circuit. The latter method is inherently more sensitive than the first and is practically the only one in use in America.

**753. The Tirrill regulator for small direct-current machines** operates as follows (see Fig. 88). The regulation depends on the rapid make and break of contacts *A* which short-circuit the resistance in the shunt field circuit of the generator. The closure of these contacts depends upon the machine voltage across the relay *B*. The contacts closed by this relay serve only to close or open one of the two differential windings on the magnet *C*, which in turn operates contacts *A* cutting in or out the field resistance. When the voltage is high, relay *B* opens one winding in *C* which in turn causes the latter to open contact *A*, inserting the resistance, and *vice versa*. The final result of operation is that the contacts vibrate continuously and remain open or closed a longer or shorter portion of the time as may be required to keep the voltage steady. A regulator of this type with multiple contacts at *A* can control machines up to 125 kw.

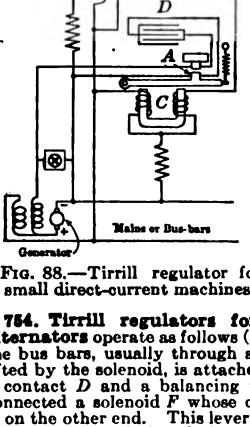

FIG. 88.—Tirrill regulator for small direct-current machines.

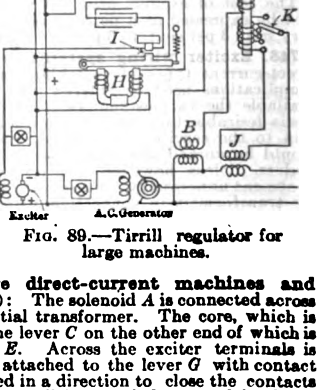

FIG. 89.—Tirrill regulator for large machines.

**754. Tirrill regulators for large direct-current machines and alternators** operate as follows (Fig. 89): The solenoid *A* is connected across the bus bars, usually through a potential transformer. The core, which is lifted by the solenoid, is attached to the lever *C* on the other end of which is a contact *D* and a balancing weight *E*. Across the exciter terminals is connected a solenoid *F* whose core is attached to the lever *G* with contact *D* on the other end. This lever is pulled in a direction to close the contacts by a spring so designed that the plunger *F* is pulled downward in direct proportion to the voltage. This arrangement gives greater sensitiveness than the simple arrangement at *B*, Fig. 88.

When the alternating voltage is low the weight of the plunger *A* overcomes that of the balancing weight *E* and closes contact *D*, causing relay *H* to close contact *I*, thus short-circuiting the field resistance and raising the exciter voltage and the alternating voltage. As the exciter voltage rises, solenoid *F* pulls down its plunger and lifts contact *D*, but as long as the alternating voltage is low, the lower contact follows. When the alternating voltage

Digitized by Google

rises above the correct value the contact $D$ is opened, which causes the resistance to be inserted again in the field circuit. The winding $K$ on the solenoid $A$ allows compounding with the load, which may compensate for the average line drop. In stations where there are several exciters, the relay $H$ operates a number of contacts $I$, one or more for each exciter. In very large stations a separate regulator is used for each exciter.

**755. Regulators with exciter batteries** are possible by the use of boosters in the exciter bus under control of the regulator, bucking or boosting the voltage supplied to the field windings.

**756. Manual regulation with regulators** is secured by varying the resistance in the circuit of solenoid $A$, Fig. 91.

**757. Protection against regulator failures** or abnormal conditions should be provided whereby excessively high or low voltage results in the operation of a relay, thereby making the regulator non-operative.

**758. Exciters for Tirrill regulators require careful adjustment for parallel operation.** Field circuits should permit voltages from 40 per cent. to 140 per cent. normal. They must respond rapidly and equally to change of resistance. Unequal response causes the quicker machine to take all the load and it may flash over.

**759. The cost of Tirrill regulators** installed is from $500 to $1,000 each, exclusive of instrument transformers.

**760. Feeder regulators** for alternating-current circuits consist essentially of compensators, the secondary winding of which is in series with the outgoing circuit. They are fully described in Sec. 6. There are two types, the contact type and the induction type, the latter being preferable. These regulators may be either single phase or polyphase as necessary. They are usually wound for ± 10 per cent. regulation. They may either be hand operated, or automatically operated through a relay and motor to compensate for line drop thus maintaining constant voltage at a distant point. The cost of 2,200 volt automatic feeder regulators for ± 10 per cent. regulation is about as follows: Single phase, $300+$350 per 100 amp. Three phase, $600+$600 per 100 amp. If motor-operated but non-automatic, about $80 is saved. Hand-operated regulators cost about $150 less than automatic.

## LOW-TENSION DIRECT-CURRENT SWITCHING

**761. Direct-current switching** may conveniently be grouped in the following **general classes**: (*a*) Single polarity; (*b*) Double polarity with equalizer on pedestal; (*c*) Double polarity with equalizer on panel; (*d*) Three wire; (*e*) Multiple voltage.

Obviously a great number of subdivisions could be made, the number of busses being the most important. Fig. 90 shows the elementary wiring of these various classes, leaving out all auxiliary wiring and all instruments.

**762. Parallel operation of compound generators** is secured by the equalizer connections which are usually of one-half to one-third the rated capacity. They parallel both terminals of all series fields, making the direction of current in all of them necessarily the same. Parallel operation is fully discussed in Sec. 8.

**763. Single-polarity switchboards** find their greatest use in railway work where the negative bus is at approximately ground potential, and is usually located in the basement beneath the machines; it should be insulated, however. The circuit breakers and instruments are in the positive side of the board and the equalizer and negative switches are on small panels or pedestals near the machines. The feeders are frequently without negative switches.

**764. Three-wire switchboards** are used for combined lighting and power systems. The generators require an equalizer on each side. If both these equalizers are thrown in, the machines are paralleled as shunt machines, so that some means must be taken to make it possible to close the equalizer switches only at the same time as the main switches. This usually calls for four-pole switches on small boards and two double-pole switches on the large, each double-pole switch consisting of one line and one equalizer switch. It is obvious that a circuit breaker and instruments are needed in each side. In the case of two-wire full voltage feeders, a double-pole circuit breaker is necessary when the neutral is grounded.

Digitized by Google

**765. The instruments required** to measure completely the output of the machines or of a feeder, comprise an ammeter or a wattmeter, or both, for each circuit-breaker shown in the diagram (Fig. 90), together with a voltmeter on the main bus. For purposes of connecting incoming generators

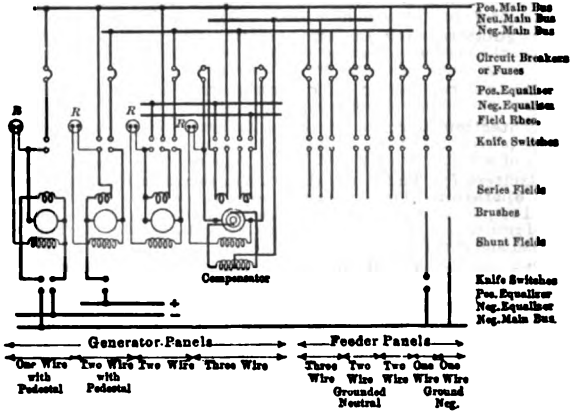

FIG. 90.—Elements of direct-current wiring.

provision must be made for a voltmeter on each machine, or a socket and plug which will enable its voltage to be measured by a common machine voltmeter. (Fig. 93.)

**766. Double-polarity switchboards** find their greatest use in power work, particularly at 250 volts. They are desirable where both bus bars must be insulated. Except for large stations there is no disadvantage in having both polarities on the same board. Except on small boards, it is desirable to have the equalizer switches on pedestals near the machines (Fig. 91).

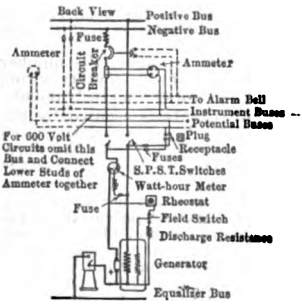

FIG. 91.—Detail wiring diagram of generator panel.

**767. Multiple-voltage switchboards** are in use where three-wire distribution is extensive. The extra busses are operated at a voltage higher than the main busses to take care of the drop in long feeders. Their voltage is usually maintained by boosters, although in some cases provision is made for connecting the generators to either set of busses.

**768. Double bus bars** are seldom warranted except for operating at two voltages. However, when there are two distinct classes of service which should be kept independent, double bus bars are desirable (Fig. 92).

**769. Spare circuit breakers** are almost necessary in heavy railway work and provision should be made for inserting them in a simple manner (Fig. 93).

**770. Auxiliary circuits** are frequently installed to accomplish many different purposes. Some of the more commonly used are as follows:

Digitized by Google

(*a*) Voltmeter bus and receptacles to enable the use of one instrument for all machines; (*b*) Current supply for instrument excitation and the operation of circuit breakers; (*c*) Signals indicating open breakers; (*d*) Remote

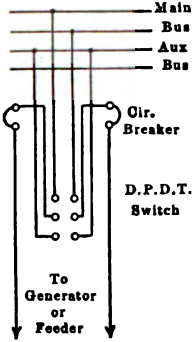

FIG. 92.

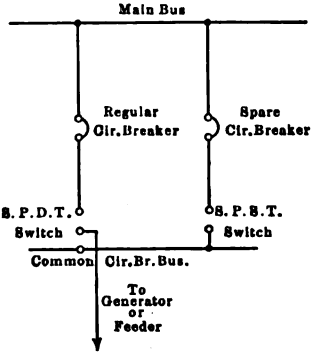

FIG. 93.

FIGS. 92 AND 93.—Wiring for spare busses and for spare circuit breakers.

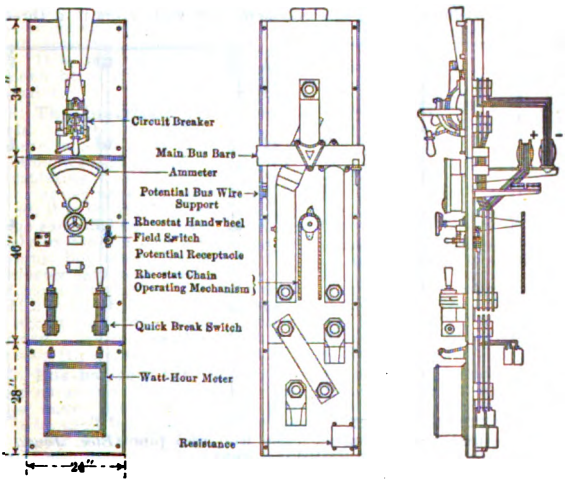

FIG. 94.—Two-pole generator panel 2500*A*, 250 *v*.

control of circuit breakers and switches; (*e*) Interlocking circuits between circuit breakers; (*f*) Reverse-current relay wring (Fig. 91).

**771. Types of switchboard panels.** The accompanying illustrations, Figs. 94 and 95, serve to indicate general types of panels. In very small in-

Digitized by Google

stallations, the generator and feeder switches may be located on the same panel. In moderate sized plants there may be several feeders per panel, although generally each generator has its own. In large systems there is sometimes a separate panel for each feeder, but this is necessary only in very special cases, usually two being grouped on each panel. The require-

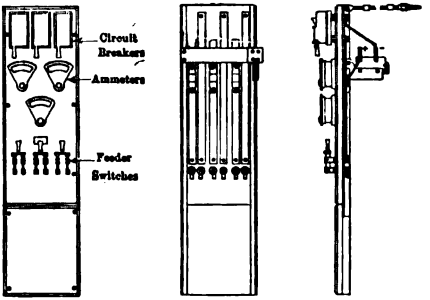

FIG. 95.—Two-wire feeder panels; three small feeders.

ments of ammeters and circuit breakers are the same both for generator and feeder panels except that occasionally two feeders running to the same point are protected with a single set of circuit breakers.

**772. Station panels** are usually provided containing a totalizing ammeter and watt-hour meter, bus voltmeter (or voltmeters if a three-wire

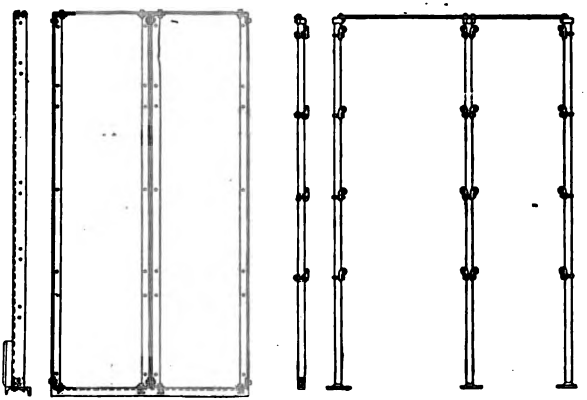

FIG. 96.—Switchboard supports; angle iron and pipe (*Elec. Jour.*, Feb., 1913, p. 168).

system), machine voltmeter and switches for auxiliary circuits and power-station lighting.

**773. Switchboard supports** are usually in the form of angle-iron framework although lately iron pipe is coming largely into use (Fig. 96). An inverted channel iron, or sill of hard wood is sunk into the floor to which the upright supports are bolted. There is an upright for each joint between

Digitized by Google

panels consisting of two angles back to back, or of a single iron pipe. Along the top is another angle or pipe. The entire board is braced in an upright position by numerous wall braces. The iron used varies in size from 2 in. × 1.5 in. × 0.25 in. to 3 in. × 2 in. × 0.25 in. One and one-fourth inch pipe is generally used. At least 3 ft. of clearance should be left between the board and the wall to allow for cleaning and repairs. In direct-current practice it is customary to insulate the iron framework from ground.

**774. Complete lines of detailed fittings** are on the market, facilitating almost any conceivable arrangement of framework for supporting the panels and bus bars. (Fig. 97.) Brackets with special insulators are used for the bus bars and longitudinal wires. Vertical small wiring is fastened to the back of the board with small straps. Vertical conductors made of copper bars or heavy wires are usually supported by the studs of the switches and the main bus bars to which they are connected.

**775. In laying out the wiring** for the switchboard panels care should be exercised to have sufficient **clearance** around all live parts (1 in. or more) and to avoid all unnecessary complications. It is important that all panels be as nearly alike as possible.

**776. The materials for panels.** Marble is used in the more important switchboards on account of its better insulating qualities and better appearance if unpainted; it is advisable if the voltage exceeds 600. Slate is likely to contain conducting veins, but when clear is a perfectly satisfactory material, considerably cheaper than marble and somewhat stronger. Panel from 1.5 in. to 2.5 in. thick are used, depending on the size of the switches and circuit breakers. In some cases even thicker reinforced panels are necessary. Marble panels complete with framework cost from $2.50 to $3 per sq. ft.; slate panels from $1.75 to $2.50.

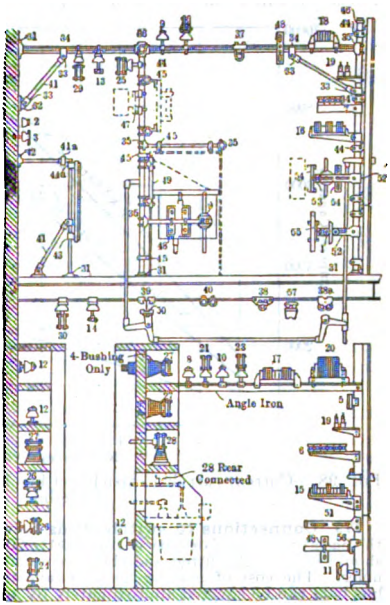

FIG. 97.—Standard switchboard details (Elec. Jour., May, 1913, p. 82).

**777. Bus-bar connections.** Bolted joints are preferable in light work, largely on account of the awkwardness of the clamps, but on heavy work, clamps have many advantages. Lap joints or butt joints with covers should be used with a uniform pressure of from 100 to 200 lb. per sq. in. The copper surfaces should be well cleaned. The **current density** in these connections should be from 100 to 200 amp. per sq. in. Under these conditions, the drop in the joint will but slightly exceed that in an equal length of bar.

**778. Bus bars** are usually made of 0.25-in. or 0.125-in. copper of various widths, seldom more than 10 in. The bars are grouped together with 0.25-in. spaces between them when using 0.25-in. copper and 0.375-in. when using 0.375-in. copper. Aluminium bars 0.25 in. and 0.375 in. thick are sometimes used. Fig. 98 shows approximately the relation between the number

Digitized by Google

of bars, the width of the bars, and the **current-carrying capacity** based on a temperature rise of 25 deg. to 30 deg. Cent. Free circulation of air is important and the bars should be supported on edge. Smaller spaces between the bars would greatly reduce their carrying capacity. In general, **current densities** of from 800 to 1,000 amp. per sq. in. are not excessive. Where aluminium is used, densities 25 per cent. less should be figured. The **cost** of copper bus bars installed will be covered in general by adding 10 cents per lb. to the cost of the copper.

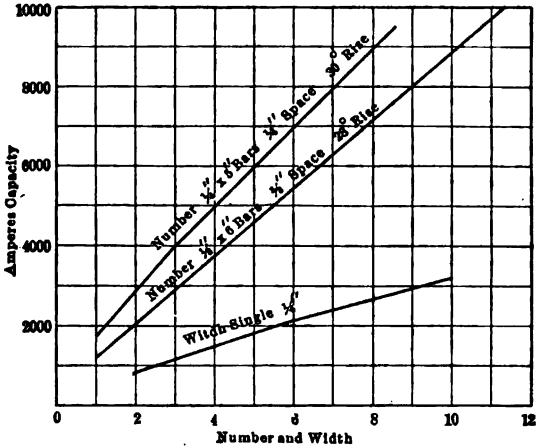

FIG. 98.—Current-carrying capacity of bus bars taken from manufacturer's bulletins.

**779. Connections to switch studs** between nuts should be figured on the basis of a current density of from 100 to 200 amp. per sq. in. Connections should be carefully fitted and the burr carefully removed from the edges of holes. The cost of making heavy connections between switch studs and bus bars can be covered approximately by adding the cost of 1 ft. of bar for each connection and 6 in. for each joint. For usual panels this work will cost about $10 per panel plus $1.50 per 100 amp.

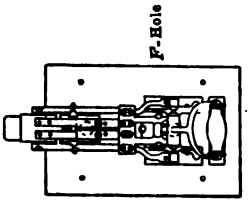
**780. Switches** should carry the maximum overload at a temperature rise of not greater than 25 deg. Cent. Current density in the blades and studs ranges from 700 to 1,000 amp. per sq. in. and in the jaws and hinges from 40 amp. to 50 amp. per sq. in. The switches must be carefully made and lined up so that the full contact area is available. If the switch overheats, the contact resistance will be greatly increased by oxidation. A 6,000-amp. single-pole switch is about the **limit of hand operation.** Very large switches with laminated brush contacts closed by toggle joints are sometimes used.

**781. Cost per pole of single-throw switches** complete with nuts, etc., ready for mounting on switchboards is $1.80 per 100 amp. of capacity; 40 per cent. should be added if the switches are double-throw; 10 per cent. should be added if they are 600-volt switches, to cover added length of blade and quick-break feature, which should always be used.

**782. Fuses** are the simplest means of automatically opening a circuit under short-circuit or overload conditions. Enclosed fuses are on the market and are approved by the fire underwriters, having capacity up to 600 amp. at 250 volts, or 400 amp. at 600 volts. Up to 30 amp., the contacts are simply ferrules on the end of the tube. On the larger fuses, contact is

Digitized by Google

made by blades fitting into jaws similar to those on knife switches. The tube is filled with heat-resisting powder which confines the arc and puts it out quickly. All fuses are supplied with indicators to show when they are blown. They will usually carry full rated load continuously, but will blow in from one to five minutes if the current exceeds 15 per cent. overload.



**783. The cost of fuses** complete with the clips is about $1 per 100 amp. capacity. The cost of the fuses alone is about 50 cents per 100 amp. capacity, and the cost of **refilling** the fuses is about 20 cents per 100 amp. capacity.

**784. Automatic circuit breakers** are required on all circuits larger than 400 to 600 amp. and even on the lighter circuits where overloads and short-circuits are likely to be frequent. There are two methods in use for preventing burning of the contacts, namely —the **carbon break** and the **magnetic blowout**. In the carbon-break method, three contacts are successively broken on the opening of a circuit. First the main current-carrying contacts open; then an auxiliary copper contact opens, and lastly a contact opens between the carbon plates and breaks the entire current, thus protecting the current-carrying contacts. In the magnetic blow-out breakers (Fig. 100) the carbon contact is replaced by a contact located between the poles of an electric magnet energized by the passage of current through these contacts. The directions of magnetic flux and current are arranged to blow the arc upward. Magnetic blow-out breakers are used in cases of extremely difficult service. In both types provision is made for the easy replacement of the auxiliary contacts.

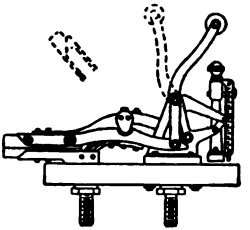


FIG. 99.—Carbon-break circuit breaker.

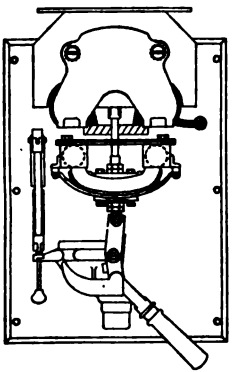
The main contacts in circuit breakers consist almost invariably of laminated copper brush bearing on flat copper blocks, and pressed down by a toggle joint exerting considerable pressure. Several types of breakers are shown in Figs. 99 to 102. The current densities used in the laminated contacts are from 400 to 500 amp. per sq. in. The entire breaker is designed for a temperature rise not to exceed 25 deg. to 30 deg. Cent. in any part.



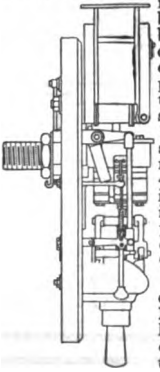


FIG. 100.—Magnetic blowout circuit breaker.

**785. Circuit breakers are ordinarily hand operated** by a lever, which is of sufficient power even for the largest sizes (Fig. 99). Frequently, however, **remote control** is desirable and electric or compressed-air operation is used. The breakers are usually arranged to reopen immediately without damage when closed on a short circuit. Motor-operated breakers are usually in pairs, one closing

Digitized by Google

before the other, so that the second is practically a switch. All breakers are supplied with an overload **tripping mechanism** which is adjustable to open the circuit at currents from 50 per cent. to 250 per cent. of rating. Other tripping arrangements may be operated by low voltage, excess voltage, reverse current of a tripping switch located at any convenient point.

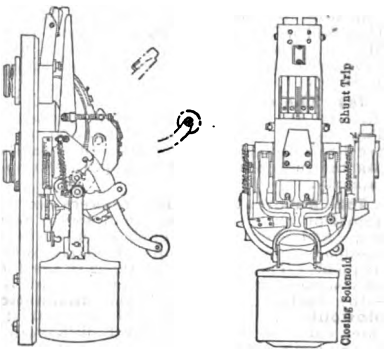

FIG. 101.—Solenoid-operated circuit breaker.

**786. Multiple-pole circuit breakers** are commonly used in the smaller capacities. For many purposes they are specially arranged so that if closed on overload or short-circuit, the tripping coil will release the closing mechanism and the breaker will open before the main contacts are closed. Such breakers may be used on feeder panels, avoiding entirely the use of knife switches.

**787. The cost of** carbon-break **circuit breakers** is about $6.00 per 100 amp. of rated capacity per pole; magnetic blow-out circuit-breakers cost about $7.50 per 100 amp. of capacity.

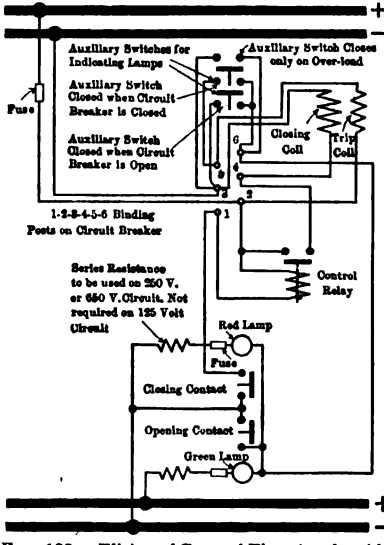

FIG. 102.—Wiring of General Electric solenoid-operated switches and circuit breakers.

**788. Switchboard instruments** in direct-current work should be carefully protected from stray fields. Wherever the bus-bar currents exceed 2,000 amp., all except the very best protected instruments will be affected, and to secure accurate readings they should be calibrated in place. It is customary to provide instruments with scales such that at the rated load of the machines, the needles will be at approximately mid-point.

**789. The cost of switchboard instruments** varies between wide limits. Ammeters may cost all the way from $15 plus $1 per 100 amp. of capacity, to $75 plus $1.20 per 100 amp. of capacity. Voltmeters may cost from $20 to $80 depending largely on the type. Watt-hour meters will vary in cost from $35 plus $1.50 per 100 amp. to $100 plus $7.50 per 100 amp.

**790. Standard switchboard panels** embodying the various devices described above and suitable for all classes of work have been developed and catalogued by the various manufacturers, so that it is now possible to buy complete, almost out of stock,

Digitized by Google

panels suitable for almost any kind of work; Fig. 96, is taken from one of these catalogues. These panels can be purchased for a lower price than it is possible to make up special panels and should be used whenever possible. The particular panels shown in this figure would cost approximately $100 plus $12 per 100 amp. without watt-hour meter, and $220 plus $16 per 100 amp. with watt-hour meter, equipped for 250 volts.

## CONSTANT-CURRENT SERIES SWITCHING

**791. Series systems** are now used in America solely for street lighting. It is probable that they will continue in use for this purpose indefinitely. The earlier installations used **series-wound generators** operating on the drooping part of the characteristic (Sec. 8). When the total pressure exceeded 2,500 volts, multiple independent armature windings and commutators were used, connected in series externally to the machine. The regulation of these machines is accomplished in two ways, by shunting the series fields or by moving the brushes, or both. Since these machines operate on the drooping part of the characteristic curve, they have considerable inherent regulation in themselves. The adjustments are made automatically by a series-connected relay or operating magnet which actuates

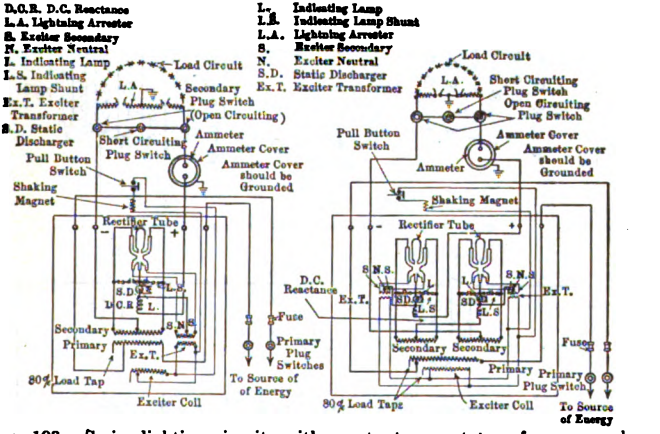

FIG. 103.—Series lighting circuits with constant-current transformers and mercury rectifiers.

the field rheostat or rocks the brushes. **Constant-current transformers** are employed very extensively for this class of service (Sec. 6) and regulate themselves almost perfectly. Each transformer is supplied with a terminal panel, etc., which forms part of the unit. Series-wound generators are installed, however, to a limited extent.

**792. Mercury-arc rectifiers** are also employed in this class of service, in connection with constant-current transformers, for series direct-curent lighting. The equipment itself is described in Sec. 6. The connections are illustrated in Fig. 103.

**793. Switching practice** is practically the same whether generators or transformers are used. Since the opening of a series circuit causes full voltage across the break, and short-circuiting causes only a relatively small increase in current, all transfers of circuits are accomplished after short-circuiting the same. Apparatus will run on short-circuit for a short time without damage. The switching is accomplished very simply by means of a transfer or carrier-bus panel as shown in Fig. 104. This arrangement is relatively inexpensive and will allow almost any conceivable switching.

Digitized by Google

**794. Ammeters** may be connected into any circuit by inserting the proper plug in the sockets in rows 1 or 11. When the plug is inserted the circuit is opened and simultaneously completed through the ammeter. In direct-

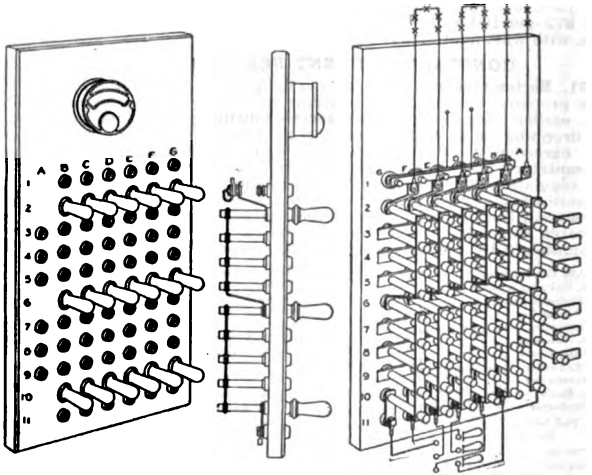

FIG. 104.—Transfer panel-series switching.

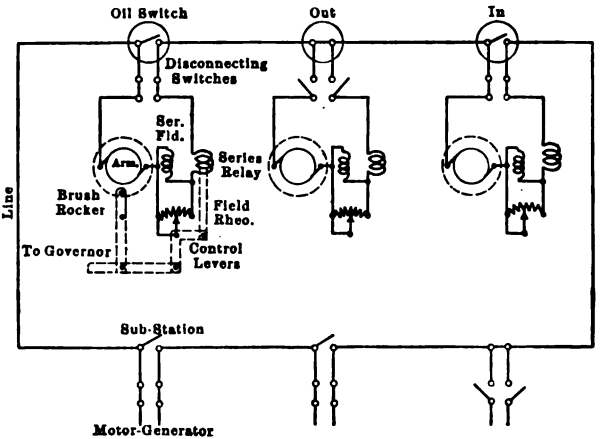

FIG. 105.—Elements of Thury system of transmission.

current work it is necessary to have the instruments in the line circuit. They must be insulated for high voltage and the cases protected with the grounded covers to protect the operator. In alternating-current work a

Digitized by Google

current (series) transformer may be used in connection with a standard instrument.

**795. The Thury system** of direct-current series transmission (Fig. 105) is not unlike the series lighting systems in use in this country. Series-wound generators are employed, developing up to 4,000 and 5,000 volts each, a sufficient number being connected in series to secure the desired transmission voltage. Currents of various magnitudes are used, approaching 200 amp. maximum. The Thury system, like our lighting systems, is essentially constant-current and is regulated to produce this condition, the voltage varying directly with the load. The system is not planned for the general distribution of energy in small quantities, but rather for transmission to substations where it is transformed to constant-potential energy. These substations are in series and each has one or more motor-generators with series-wound motors. This system has not been received with favor in this country.

**796. The insulation of the machine windings.** (Thury system) need not be for the full voltage. If a small number of machines is contemplated, this insulation could probably be advantageously used, but in large systems of high voltage and numerous machines, the most economical results may be expected by insulating each machine from the ground and from other machines. The difficulty lies largely in securing an insulating coupling combining mechanical with dielectric strength. The machines must each be surrounded by a highly insulated platform so constructed as to allow easy access without danger to the operators.

**797. The switching** (Thury system) may be exceedingly simple, as no automatic circuit-interrupting devices are required or even desired. Since the characteristics of series generators permit short-circuit currents but slightly in excess of the operating currents, no devices for protecting against excessive currents are necessary. It is probable that satisfactory switching can be secured by hand-operated non-automatic single-pole switches, one to short-circuit the terminals of the machines and two others to disconnect it from the line (Fig. 105). None of the complications usual in constant-potential systems need be considered. The short-circuiting switch should have a rupturing capacity equal to the rating of a single generator. The disconnecting switches may be of the ordinary air-break type, but insulated for the total voltage of the system. This insulation is necessary so that the machines may be disconnected from the lines and grounded for repairs.

**798. The regulation** (Thury system) consists in maintaining constant current and can be secured in three ways, any combination of which may be used: (*a*) shunting the series fields by an adjustable rheostat; (*b*) rocking the brushes from the neutral point; (*c*) controlling the speed. The difficulties of commutation prevent any very considerable adjustment by the first two methods, but the generators themselves are self-regulating in a large degree. The automatic regulation is secured by a series relay which operates the field rheostat or other controlling means through direct connection or by electric control. Large adjustments are taken care of by the starting up or shutting down of machines. Motors are regulated to give constant speed by centrifugal governors which actuate the field rheostat and rock the brushes. Protective devices are required for short-circuiting the terminals when the voltage exceeds rating.

## ALTERNATING-CURRENT SWITCHING

**799. The principles of alternating-current switching** are not necessarily different from those of direct-current (Par. 761 to 790). The same equipment and apparatus may be used for low-voltage work, except for slight modifications to avoid eddy currents. The elements of alternating-current switching arrangements are shown somewhat progressively in Fig. 106. The symbols indicate **oil switches**, (*O*) capable of being opened under load and **disconnecting switches** (*X*) incapable of interrupting any except the smallest currents.

The simplest arrangement is that shown in sketch *A* (Fig. 106), where the generators and feeders are grouped at either end of a single bus. Sketches *B* to *E* indicate arrangements for **sectionalizing the bus** by disconnecting switches, which permit the division of the plant at any desired point; some sectionalization by oil switches is frequently desirable. The

Digitized by Google

**ring bus** shown at *E* probably has the greatest advantage. **Double busses** are shown at *F*, *G* and *H*, which have the added advantage that any group of feeders may be supplied from any group of machines; double-throw disconnecting switches, and double-throw oil switches are shown, but the latter are not recommended. The **relay bus** system shown at *L* and *M* gives some control of the sectionalising under load.

The need for increased reliability of switching, as well as increased flexibility has led to the arrangements shown at *I* to *R* inclusive; sketch *I* shows spare oil switches arranged to replace any of the others, through disconnecting switches. In the other layouts, there is usually a spare switch for each generator or feeder group, so that no equipment need be kept out of service on account of switch trouble alone. Obviously, switching arrangements without limit can be devised to allow almost any conceivable switching operation.

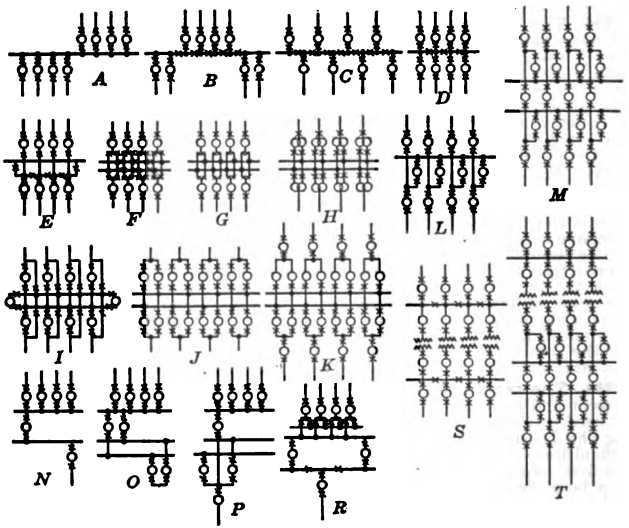

FIG. 106.—Elements of alternating-current switching.

**800. Group switching** is usually resorted to (Figs. 106*N* and 106*R*) in very large stations of moderate voltage, where the number of feeders is relatively large. It facilitates starting after a shut-down, and simplifies the sectionalization of the loads for any purpose. It also provides the maximum of flexibility with a minimum of expensive oil switches.

**801. High-tension power stations** using transformers require both high-tension and low-tension bus systems. The great expense of high-tension switches and the large space necessary for their enclosure has led to very simple high-tension layouts. For example, the Ontario Power Company employs the complicated low-tension layout *M* and the simple high-tension layout *D* (T Fig. 106).

**802. The grounded neutral** has proved advantageous principally in systems having extensive underground distribution, the object being to open the circuit breaker of a grounded feeder before a short-circuit between phases can occur. A resistance is usually inserted between the neutral bus and the ground, of such magnitude that the current flowing to a grounded feeder will comfortably operate its overload relays. When

Digitized by Google

three-phase star-connected generators have a third harmonic in the e.m.f. wave, it will appear as a voltage between neutral and ground. Where dissimilar machines are operated in parallel, a considerable voltage may develop between their neutrals which will make their interconnection dangerous. In such cases it is necessary to introduce resistance in these connections. It is common practice, however, to operate with but a single machine grounded, which prevents interchange of neutral current and still protects the system.

**803. Current-limiting reactances** are coming into use on large systems to limit short-circuit currents, thus protecting generators and limiting the duty of the oil switches. These reactances are of the air-core type (6). They are used in two ways: those permanently inserted in the circuits, and those inserted only during switching operations. The ordinary turbo-generator will deliver instantaneously on short-circuit, from 30 to 50 times rated full-load current; a reactance sufficient to reduce this to 15 times full-load is apparently all that is necessary in present installations. This reactance may be introduced in the machine leads, in the bus bars, or in the feeders. The first method is commonly used for permanent insertion in very large stations; these reactances are quite large and expensive. The second method is recommended for use between sections of the bus in stations where the switches would otherwise be inadequate. The third method is used for insertion of reactance only during the opening of a short-circuit; there are two switches in series, the first inserting the reactance (normally short-circuited), thus limiting the current to be broken by the second which is mechanically interlocked to open immediately afterward. These reactances are small and may even be included in the oil pots of large switches.

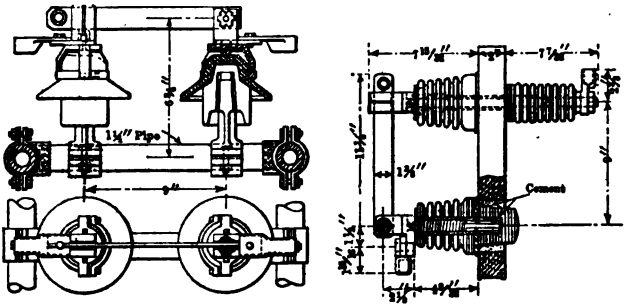

FIG. 107.—Disconnecting switches.

**804. Disconnecting switches** (Fig. 107) are ordinarily used for sectionalising bus bars or circuits, or for isolating apparatus for grounding or repair, but not for switching under load. They are used sometimes, however, in place of oil switches on one side of parallel transformer banks. Disconnecting switches should not be located to open downward unless locks are provided to keep them from jarring out. In very heavy work care should be used to avoid loops in the wiring which on short-circuits will produce magnetic forces sufficient to open the switch. The cost of 300-amp. disconnecting switches is about $5+$0.50 per 1,000 volts. The cost of 600-amp. disconnecting switches is about $10+$0.60 per 1,000 volts.

**805. Expulsion fuses** (Fig. 108) are used for connecting potential or small auxiliary transformers to the bus. They are usually arranged also as disconnecting switches. They consist essentially of fine fuse wire confined in strong insulating tubes closed at the lower ends. The blowing of the fuse and the resulting confined arc suffice to blow the conducting vapors out of the open end, thus putting out the arc. The tubes are arranged for con-

venient removal and refilling. They are recommended only in small capacities and moderate voltages, although they are offered up to 60,000 volts, 20 amp. They cost about $20 plus $0.30 per 1,000 volts.

**806. Oil circuit breakers** are used for interrupting current at all voltages above 600. Three of the numerous types of oil switches are shown in Figs. 109 to 111. The contacts open under oil and the arc is put out by the cooling action, and the pressure of the oil. When a circuit is opened the resulting

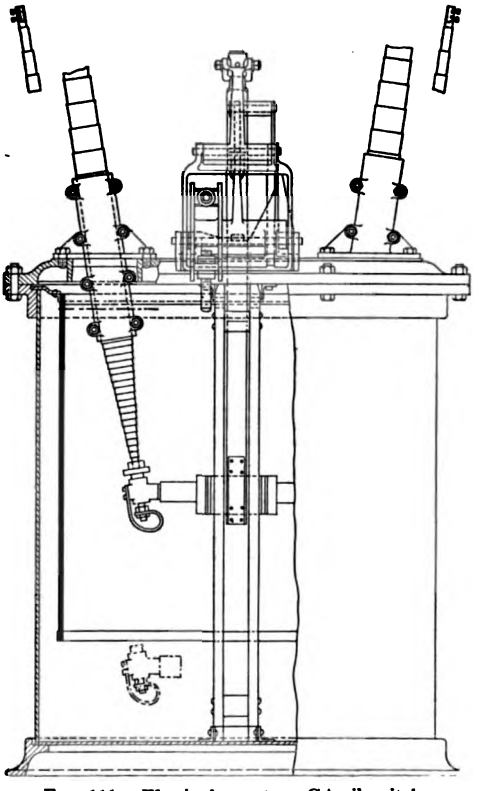

FIG. 111.—Westinghouse type GA oil switch.

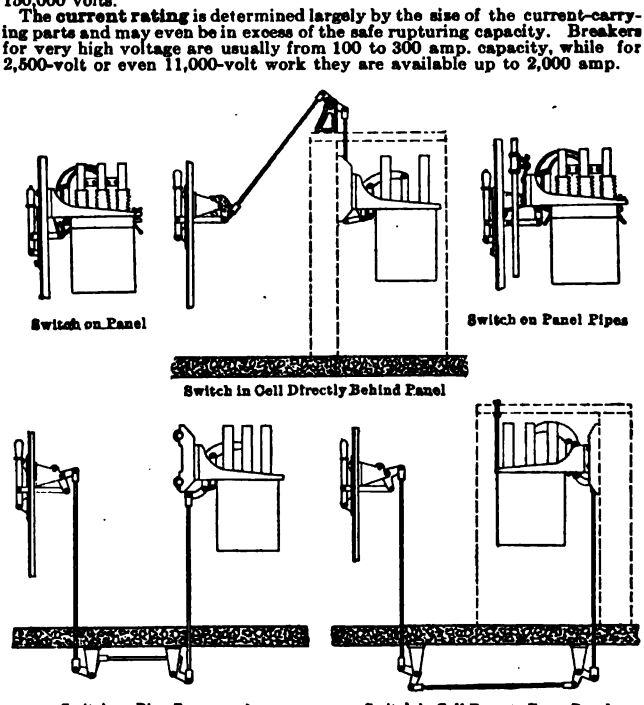
arc tends to impart a more or less violent motion to the oil, away from the contacts, but its inertia and pressure due to depth resist the action and quickly quench the arc. This pressure becomes very great in violent short-circuit interruptions, and has been observed as high as 150 lb. per sq. in. a few in. away from the arc. Contacts of various types are used and all have certain advantages; many are arranged with auxiliary contact for the final breaking of the circuit. Most of the breakers are arranged to open by gravity.

Digitized by Google

A special **circuit-breaker oil** is used which is fluid at low temperatures and is free from moisture. The oil level must be carefully maintained in operation, and the oil must be changed when burned by short circuits.

**807. The temperature rise** should never exceed 25 deg. to 30 deg. Cent. in the hottest part at continuous full-load. The **voltage rating** is determined by the insulation distance to the grounded parts and by the breaking distance of the contacts. The Westinghouse Company designs its high-capacity high-voltage breakers, with a ground distance of about 5 in. plus 0.25 in. per 1,000 volts, and with a total breaking distance per pole of about 10 in. plus 0.33 in. per 1,000 volts. Breakers are available up to 150,000 volts.

The **current rating** is determined largely by the size of the current-carrying parts and may even be in excess of the safe rupturing capacity. Breakers for very high voltage are usually from 100 to 300 amp. capacity, while for 2,500-volt or even 11,000-volt work they are available up to 2,000 amp.



Switch on Panel
Switch on Panel Pipes
Switch in Cell Directly Behind Panel
Switch on Pipe Framework
Switch in Cell Remote From Panel

FIG. 112.—Mountings for small oil switches.

**808. Oil switches for panel mounting** (Fig. 112) usually have their poles enclosed in a common grounded rectangular steel oil-filled tank which is removable by dropping it away from the contacts. This type, when mounted on panels, is not desirable above 2,500 volts and 3,000 kw. station capacity.

**809. Wall and framework mounting** (Fig. 112) with remote control, using this same type of switch (Par. 810), extends its capacity to about 12,000 kw. at 2,500 volts, or to 6,000 kw. at 15,000 volts.

**811. Remote control.** In most cases **electrical control** is used where hand control is undesirable. The operation in most types is secured by solenoids, a powerful one closing the switch, and a lighter one releasing a latch which permits the switch to open by gravity. In the General Electric type *H* switch (Fig. 110) a motor is employed for the purpose of winding a spring which on the release of a stop by a solenoid closes or opens the switch, depending on its position. Following the operation of the switch the motor again winds up the spring. **Pneumatic control** is used in some cases in very high-voltage work. For wiring see Figs. 102 and 113.

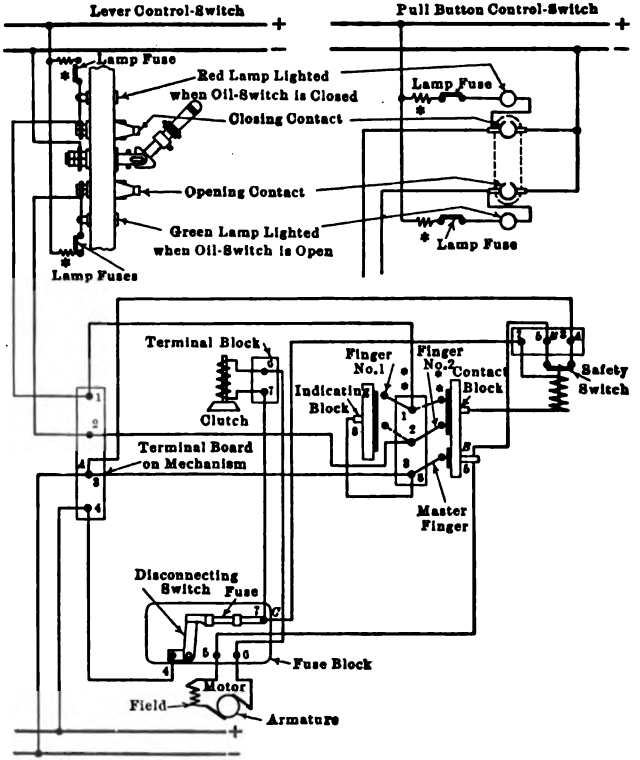

FIG. 113.—Wiring of General Electric type H oil switch.

**812. The ultimate breaking capacity of oil circuit-breakers** is determined by a great number of variables and the term itself is not very definite. The manufacturers use for this term the maximum size of station in which they recommend the breaker. Obviously this is not the ultimate breaking capacity. A breaker would be safe in a station of low speed units giving low instantaneous short-circuit current, while it might be destroyed in a turbo-generator station of the same size. Important factors determining this rating are voltage, length of break, size and strength of oil tank,

Digitized by Google

control of the oil, etc. Generally breakers with a separate tank per pole, or with a separate tank for each contact have larger breaking capacity than those where all the poles and contacts are grouped in one tank. A breaker operated at less than standard voltage will have its ultimate breaking capacity somewhat increased.

**813. Hand control of oil switches** is used for panel-mounted switches and for remotely mounted switches, in the smaller stations. The remote control is secured through bell cranks and rods (Fig. 112). Where the switches become numerous and are too far away, or the station is of too large capacity, hand operation is undesirable.

**814. Oil switches for floor mounting** (Fig. 111) have each pole enclosed in a heavy grounded tank and may be supplied with weather-proof entrance bushings and cast-iron covers for the operating mechanism, allowing use out of doors. They are available for voltages from 25,000 to 150,000 and are suitable for stations of almost any size.

**816. Switches for oil mounting** cover: (*a*) the above type where such mounting increases the safe rupturing capacity about 15 per cent. (*b*) a modification of this type with individual and stronger tanks for each pole, sometimes with separate cells for each pole, which is suitable to 40,000 kw. and 2,500 volts, or even higher with special design; (*c*) switches having two separate round pots per pole each containing a separate contact, and each pole in a separate cell, which are suitable for all capacities, particularly up to 25,000 volts.

**817. The source of energy for operating switches** should be of utmost reliability. Storage batteries are almost invariably used except in small stations where the exciter system is used. All switching mechanisms should be designed to operate satisfactorily on a range of voltage from 40 per cent. below to 20 per cent. above normal.

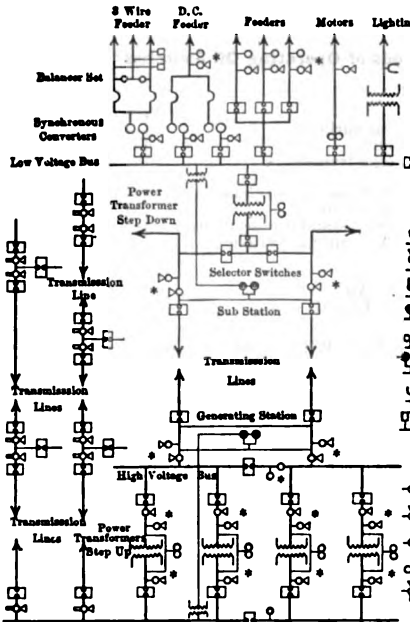

FIG. 114.—Use of relays (Hewlett, *Trans.* A. I. E. E., Mar., 1912).

**818. Relays** are used operating under all of the conditions outlined in, Par. **816**. The most common arrangements are shown in Fig. 114 (E. M. Hewlett, *Trans.* A. I. E. E., March, 1912). The most common types are: the solenoid with plunger and the meter type very similar to the induction meter. Adjustment for current is made by position of plunger in first type and by strength of spring in second. Adjustment for time is made by bellows or oil pot resisting motion of plunger or disc and magnets resisting turning of

Digitized by Google

armature of motor type. Definite time limit is secured by clockwork. Usual adjustments by bellows or magnet give a time in inversely as the actuating force.

It is important that under short circuit conditions relative settings remain unchanged. **The cost of three pole relays** varies from $25 for plain overload instantaneous to $60 for reverse current inverse time limit. Some types cost this amount per pole and special types are considerably more expensive.

**819. The cost of oil switches** varies between exceedingly wide limits, depending largely on rupturing capacity and voltage. Some idea of the costs may be obtained from the following three-phase non-automatic switches: For small systems up to about 5,000 kw. and 2,500 volts, about $20 plus $4 per 100 amp. capacity; for larger systems of say, 12,000 kw. and 2,500 volts, or 6,000 kw. and 15,000 volts, about $70 plus $10 per 100 amp.; for very large systems of 25,000 volts or lower, roughly $600 plus $20 per 100 amp. hand operation being unavailable. For very high voltage systems there is usually only one current rating for each voltage; such switches for 44,000 volts will cost from $400 for a 15,000-kw. rating, to $1,200 for a 50,000-kw. rating; for 110,000 volts, from $1,500 for a 15,000-kw. rating to $2,500 for a 50,000-kw. rating. The cost of electric operation is about $50 additional, exclusive of control wiring.

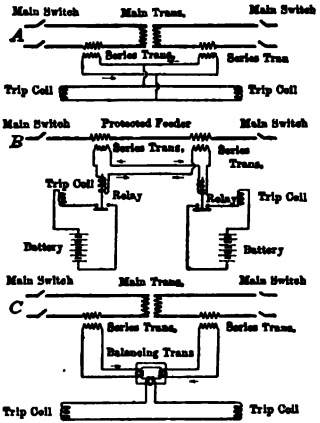

FIG. 115.—Merts-Price systems of protecting transformers and cables.

**820. Merts-Price System of relay protection** depends on unequal currents at two ends of conductor in trouble. The series transformers at the two ends are interconnected so that, normally, no current flows through the relay. Unbalance due to trouble cuts out the apparatus (Fig. 115).

**821. Instrument equipment for generator panels** includes: (*a*) One alternating-current ammeter (where phases are likely to be unbalanced an ammeter is often supplied for each independent phase, or current transformers and transfer switches for connecting the single ammeter to any phase; (*b*) one alternating-current voltmenter (or voltmeter receptacle and plug to connect to common voltmeter); (*c*) one direct-current field ammeter (optional); (*d*) one indicating wattmeter (needed for parallel operation); (*e*) one power-factor meter (or wattless kv-a. indicator, optional); (*f*) one frequency meter (optional); (*g*) one ground detector (not common); (*h*) one watt-hour meter (optional but desirable); (*i*) one synchronising outfit; (*j*) current (series) and potential (shunt) transformers; (*k*) one automatic relay (optional).

**822. Instrument equipment for feeder panels** includes: (*a*) One alternating-current ammeter (ammeter transfer switches may be used if phases are unbalanced); (*b*) one indicating watt meter (optional); (*c*) one automatic relay; (*d*) current (series) transformers.

**823. Instrument equipment for station panel** includes: (*a*) Synchroniser (extra one optional); (*b*) voltmeters for each phase of each bus (optional); (*c*) frequency meter; (*d*) voltage regulator (optional); (*e*) totalising wattmeter (optional); (*f*) totalising watt-hour meter (optional).

**824. The cost of high-grade switchboard instruments** mounted with panel wiring, but exclusive of instrument transformers, is about as follows: ammeters $40, voltmeter $45, single-phase wattmeters $50, poly-

Digitized by Google

phase wattmeters $70, single-phase watt-hour meters $70, polyphase watt-hour meters $125. Large variations in price however exist between various types and grades.

**825. The synchronizing equipment** in a station must be ample enough to prevent any possibility of failure, and should be in duplicate in all except small stations; there should also be synchronizing lamps in case of failure of the instruments. There should be more than one set of instrument transformers available for the bus voltage. Synchroniser wiring should preferably be as simple as possible (Fig. 116).

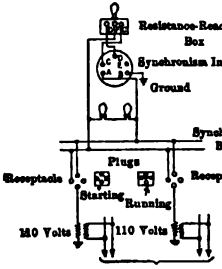

FIG. 116.—Synchroniser wiring using shunt transformers.

**826. Instrument transformers** (Sec. 6, and Sec. 3) are generally used whenever the currents exceed 100 amp. or the voltage 600. They are designed for 5 amp. and 110-volt secondary. Separate transformers of ample capacity should be provided for relays and for instruments. Potential (shunt) transformers are usually oil insulated for all voltages above 4,000 and current (series) transformers for voltages above 15,000. Instrument transformer wiring must be grounded thoroughly, both at the transformer and at the board, to prevent high potential on the panels in case of burnouts.

**827. The cost of high-grade instrument transformers** is about as follows:

Series type, 2,500 volts, $10 + $0.60 per 100 amp.; 11,000 volts, $30 + $2 per 100 amp.; 33,000 volts, $60 + $18.00 per 100 amp.; 66,000 volts, $175 + $35 per 100 amp.; shunt type, 200-watt size, $20 + $8 per 1,000 volts.

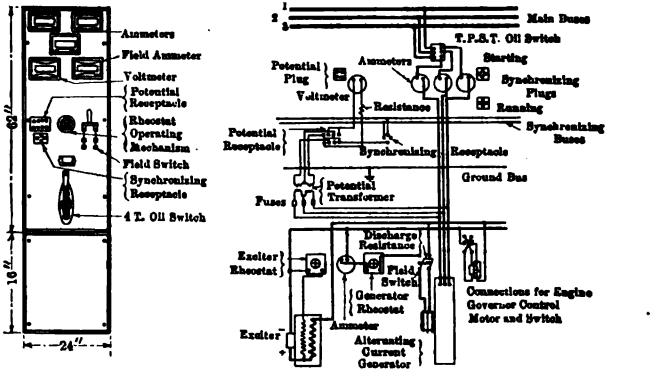

FIG. 117.—Three-phase generator panel.

**828. Types of switchboards** using the apparatus above described may be divided into three classes:

1. Self-contained panel type.
2. Remote mechanically operated: (*a*) panel boards; (*b*) bench boards.
3. Electrically operated: (*a*) panel boards; (*b*) bench boards.

The capacity and voltage of the station largely determine the type as discussed under oil switches, type 1 being suitable for the smallest and type 3 for the largest systems. Space requirements for the different

Digitized by Google

types are not materially different. Typical panels are shown in Figs. 117 to 120.

**829. Relative costs of switchboards** are approximately 100 per cent. for type 1, 120 per cent. for type 2 and 140 per cent. for type 3 (Par. 828). These figures are approximate only for the same electrical layout, whereas different layouts would undoubtedly be used for the stations for which each type would be suitable. The following table gives the costs of typical panels shown in Figs. 121 to 123.

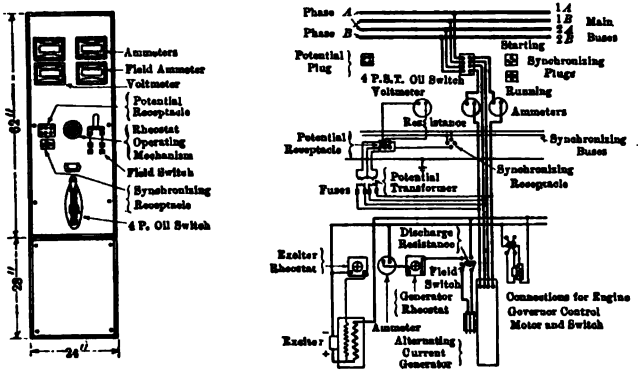

FIG. 118.—Quarter-phase generator panel.

**830. Approximate Cost of Switchboard Panels**
C. H. Sanderson, *Elec. Jour.*, 1913.

| Kind of panel | Volts | Amps. | Fig. | Cost | U.B.C.* |
|---|---|---|---|---|---|
| Generator | 2,200 | " | 121 | 440 | 9,200 |
| | 6,600 | " | | 385 | 7,800 |
| Feeder | 2,200 | " | 121 | 345 | 9,200 |
| | 6,600 | " | | 350 | 7,800 |
| Generator | 2,200 | " | 122 | 360 | 9,200 |
| | 6,600 | " | | 310 | 7,800 |
| Feeder | 2,200 | " | 122 | 260 | 9,200 |
| | 6,600 | " | | 265 | 7,800 |
| Generator | 11,000 | " | 123 | 1,240 | 12,500 |
| | 6,600 | " | | 1,130 | 15,500 |
| Feeder | 11,000 | " | 123 | 1,045 | 12,500 |
| | 6,000 | " | | 940 | 15,500 |

**831. Cost of switchboards.** Switchboards generally cost from $2 to $8 per kw. of capacity including all wiring and apparatus installed.

**832. Mimic or miniature bus bars** are invariably installed on the faces of the control boards in large stations. They represent by single bars exactly the electrical relation of the main switch controlled by each control switch and thus greatly simplify the operation.

**833. Grouping of panels.** It is customary to arrange the panels as follows, beginning at one end; voltage regulator, exciters, station auxiliaries, generators, feeders, with blank panels sufficient to care for any reasonable extension of the plant. With remote control, particularly electrical, this

* U. B. C. = Ultimate breaking capacity of circuit breakers set for instantaneous trip. Costs include all apparatus necessary and all structures shown but no wiring. Add 10 to 20 per cent. to cover installation.

Digitized by Google

arrangement of the switches themselves may be impossible on account of desired electrical layout, but the panels may be so arranged to advantage. Remote-control bus structures and switches should be located where there is room for considerable extension.

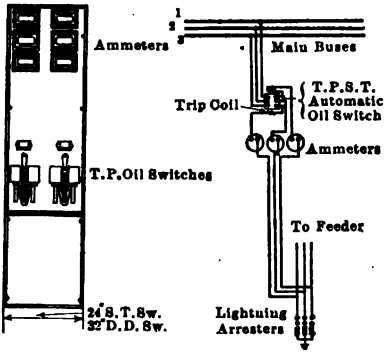

FIG. 119.—Three-phase feeder panel.

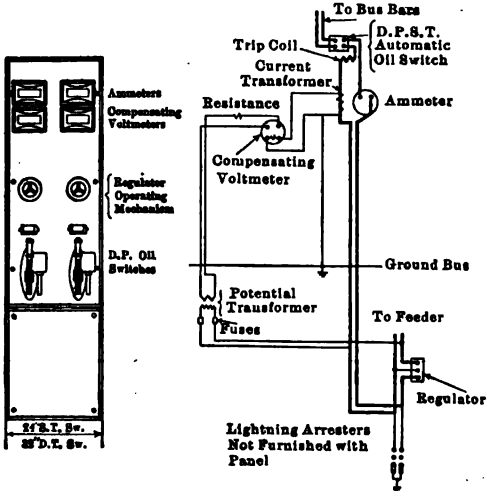

FIG. 120.—Single-phase feeder panel.

**834. The operation and care of switchboards.** Small stations up to say 5,000 kw. do not need any special operators for the switchboard. The engineer on watch has ample time to take care of any switching operations. With larger stations special operators become necessary; up to 10,000 kw. one

Digitized by Google

operator on a watch is enough and, during the light load periods, if the arrangement of the board with respect to the turbine room is suitable, this operator may be unnecessary. Above 10,000 kw. an operator continuously on watch is necessary and frequently an additional man to take care of disconnecting switches and the cleaning and repair of oil switches. Above 20,000 kw. it is customary to have additional men until in the very large stations, there are never less than two men on the board at all times.

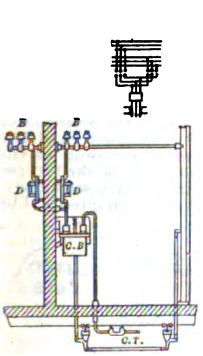

FIG. 121.

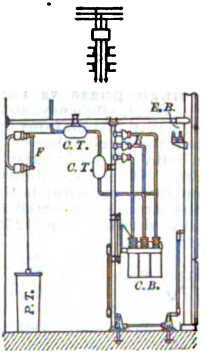

FIG. 122.

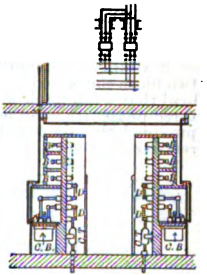

FIG. 123.

**835. Bench boards** are used only in large stations where the number of circuits is very large. A great saving in space is possible because the instruments do not crowd the control switches, thus allowing two or more generators to be handled on a single panel. Some of the types are shown in Fig. 124.

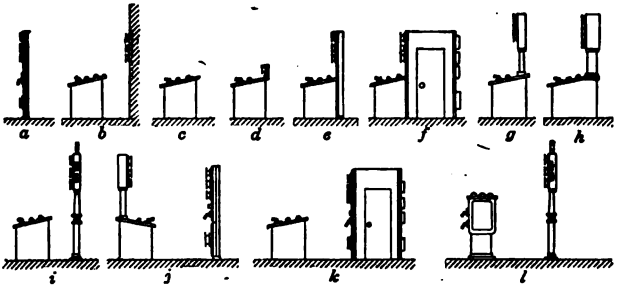

FIG. 124.—Types of bench boards.

**836. Load dispatching** in some form is necessary on complicated systems. The load dispatcher has full control over and knowledge at all times of the condition of the system. He usually has a map of the system indicating the condition of all electrical apparatus and issues all orders by telephone for the putting on or taking off of any machine or cable. Emergency conditions require a certain suspension of the direct control of the dispatcher, but in such cases a carefully worked out routine must be followed. Some very large systems have no man formally called a dispatcher but in such cases the senior operator in the largest station is given final authority and his orders must be obeyed.

## STATION TRANSFORMER INSTALLATIONS

**837. Transformers of practically all types** are used for high-tension power-station work. On account of the size and voltage of most stations of this kind, the main power transformers are usually oil insulated, with or without water cooling, and of the shell type of construction. See Sec. 6.

**838. Air-blast transformers** are rarely used above 15,000 volts and in sizes above 1000 kv-a. They are available, however, up to 33,000 volts and 2,500 kv-a. These extremes should be avoided on account of insulation and cooling difficulty.

**839. Self-cooled transformers** are built in sizes up to about 2,000 kv-a. but the space required is large on account of the necessity of outside cooling tubes. Up to 1,000 kv-a. corrugated tanks give satisfactory results.

**840. The question of single-phase vs three-phase transformers** is not definitely settled. First cost, efficiency, simplicity of wiring and floor space, all point to the latter, but in installations of few units the desirability of flexibility frequently dictates single phase. When operated in delta, two units connected in open delta will safely carry about 60 per cent. of the load that a full bank will carry. This same ability also exists in shell type, three-phase transformers operated in delta, both primary and secondary, provided the damaged coils are disconnected and short-circuited. The relative floor space occupied is shown in Fig. 125.

Single Phase Water-Cooled Transformers Total Capacity 6000 Kv-A

Three Phase Water-Cooled Transformers Total Capacity 6000 Kv-A

Single Phase Air-Blast Transformers Total Capacity 6000 Kv-A

Three Phase Air-Blast Transformers Total Capacity 6000 Kv-A

FIG. 125.—Relative floor space of single-phase and of three-phase transformers (G.E. Bulletins).

**841. Water cooling** is most generally used in large installations. The water supply must be continuous and pure. Where cooling water must be purchased cooling towers can be used to advantage. It is desirable to have negative pressure in the cooling pipes to prevent leakage into the oil.

**842. The amount of water** required is approximately 4 gal. per min. per 1,000 kv-a. capacity. This amount is not rigid. In winter considerably less is necessary, and in summer fully twice as much can be used to advantage.

**843. The cost of water-cooling systems** is from 10 cents to 25 cents per kv-a., depending on the source of supply.

Digitized by Google

**844. Air-cooling requires blowers** taking about 0.25 per cent. of the output. They are usually electrically driven and require from 3 cu. ft. per min. to 5 cu. ft. per min. per kv-a. at pressures from 1 oz. per sq. in. to 0.5 oz. per sq. in., depending on size. The first figures are for 100 kv-a. size and the latter for 1,000 kv-a. size.

**845. Oil-insulated transformers** are in reliable service up to 110,000 volts and 14,000 kv-a. and down to very small sizes at 25,000 volts. They are the most satisfactory in the average central station.

**846. Forced oil cooling** can be used for all sizes and gives satisfactory results. The transformers usually have plain boiler iron shells. The oil is pumped in at the bottom and overflows at the top, passing through a glass sight tubes to cooling coils located where good air circulation or cooling water is available. This method avoids the possibility of water leaking into the oil through defective tubes, as the oil may be kept under slight pressure. It also allows the convenient drawing of the shells without special piping. The chief objection is that a fire may put the entire equipment out of service. The cost is from 25 cents to 50 cents per kv-a. of capacity, which is considerably higher than water cooling, but there is a considerable saving in the cost of the transformers due to absence of cooling coils.

**847. Fire danger** from transformers, while not negligible, has been greatly exaggerated in the past. In some installations each bank has been placed in a well-drained fire-proof chamber, in addition to being equipped with a piping system to enable the rapid emptying of the shells into a buried tank. Some of the latest and very important installations have been constructed with simple barriers between banks opening into a common passage. The drainage system is still important but is used principally to facilitate repairs, inspection and the treating of the oil.

**848. Convenient handling** of the transformers should be provided for either by an overhead travelling crane, or by mounting on trucks on which they may be moved to an inspection pit.

**849. Transformer oil must be kept particularly free from moisture;** one part in 10,000 will reduce the dielectric strength 50 per cent. Drying outfits, which dry the oil by forcing it through successive sheets of blotting paper, are available at a cost of from $500 to $1,000 with capacities of from 5 to 20 gal. per min.

## LIGHTNING ARRESTERS

**850. Lightning protective apparatus** is used in power stations to protect the apparatus therein from abnormal potentials on the system, whether caused by lightning disturbances or by switching operations. The ideal apparatus will immediately relieve the system of excess voltages, allowing no flow of the dynamic current of the system, and be ready for immediate service again.

**851. The magnetic blow-out principle** is frequently employed, particularly in low-voltage arresters. The spark gap is placed between the poles of an electromagnet (Fig. 126) excited by the flow of current which immediately bows out the arc. Series resistances are usually employed with this arrangement.

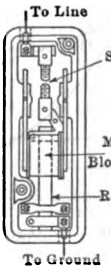

FIG. 126.—Magnetic blowout lightning arrester for low voltage.

**852. Choke coils** are simple open air core reactors inserted between the arresters and the apparatus to be protected to choke back the lightning disturbances, which are of very high frequency, thus allowing the arrester to discharge with a minimum strain on the station apparatus. To secure the full benefit of the choke coils, the connections to the arresters should be as straight as possible.

**853. Spark gaps** are used in practically all types of arresters, set at sufficient distance to prevent sparking over at ordinary voltages. Obviously something additional is needed to limit the flow of dynamic current after relieving the excess potential. Their most common use without considerable modification is to protect transformer secondaries, a single gap per bank of transformers being used.

Digitized by Google

**854. Series resistances** are usually inserted between simple spark gaps and ground for the purpose of arresting the current. This is accomplished, however, at a sacrifice in efficiency of the arrester in removing the disturbances which frequently have considerable current volume. This method is used, however, in many types from the lowest to the highest voltage.

**855. Fuses inserted in series with a gap** (Fig. 127) are not uncommon. They serve to relieve the system and interrupt the current, but they have the serious disadvantage of being able to handle only a single discharge. A simple circuit breaker is sometimes similarly used on low-voltage systems.

All of the above arrangements have their simplicity to recommend them but they are inadequate on all but very small or low-voltage systems.

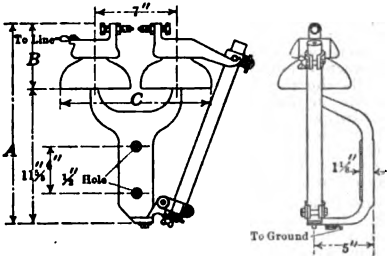

FIG. 127.—Air gap lightning arrester with fuse.

**856. Horn gaps** are modified spark gaps which consist of conductors arranged in a "V" with a suitable gap at the bottom. The flaring sides are shaped so that the arc in rising by the heated air is lengthened and finally blown out. Careful proportioning is necessary, but even then the horns will fail to put out the arc from a heavy current.

**857. Multigaps**, which consist of a large number of gaps in series, between relatively large cylinders of non-arcing (composition) metal, have many advantages. When placed between line and ground the potential drop be-

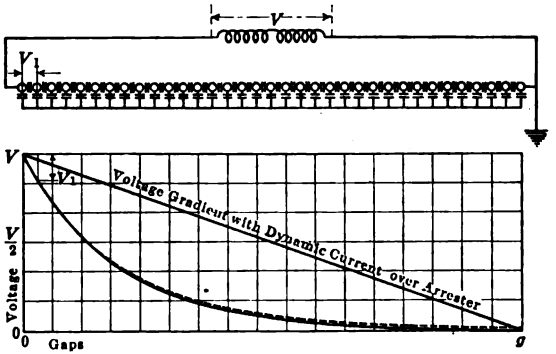

FIG. 128.—Voltage gradient across multigap arrester with and without dynamic current.

tween gaps is much greater near the line than near the ground, due to the electrostatic capacity of the cylinders (Fig. 128). This makes possible a much greater aggregate gap distance than with a single gap, which greatly aids the quenching of the dynamic arc. Lightning disturbances, being of high frequency, cause a still greater potential gradient, which will allow the disturbances to pass at a relatively low excess voltage. As soon as the gaps break down the flow of current causes an equal drop in all gaps.

Digitized by Google

The non-arcing metal has a low boiling point and acts as a rectifier, not allowing the dynamic arc to be resumed on reversal of current, if the voltage is kept low enough. The greater the number of gaps in series the more definite this action.

**858. Multipath arresters** allow high voltages to discharge along the surface of a very high resistance rod in numerous very fine sparks, the normal voltage being unable to continue the arc. This type is limited to small discharges.

**860. Graded shunt resistance combined with multigaps,** allows a greatly increased effective number. Referring to Fig. 129, which shows the arrangement used by the General Electric Co., the full line voltage is normally across the lower group of gaps, the resistance being low enough to accomplish this result. When breaking down, the flow of current through the high resistance causes a

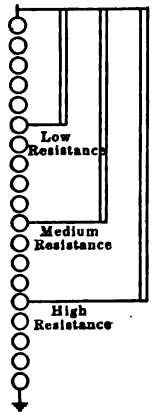

FIG. 129.—Elements of graded shunt multigap arrester.

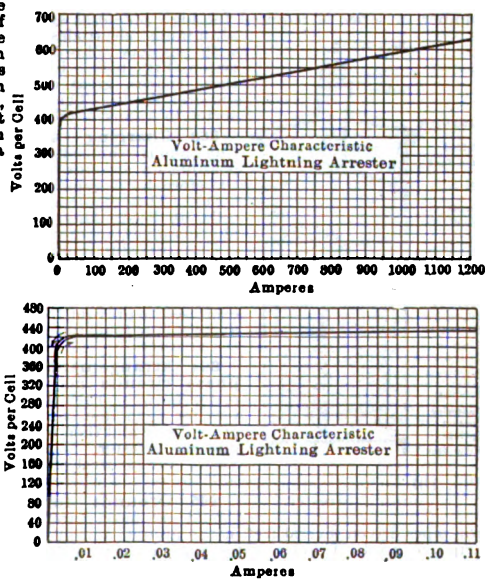

FIG. 130.—Characteristics of aluminum lightning arrester.

voltage across the second lower group of gaps which; if the lightning discharge is heavy enough, are broken down, thus inserting additional gaps to quench the arc. Similarly if the arc continues due to the discharge being too heavy, additional gaps are inserted until the entire group is in series. If this number will not rupture the arc the arrester may be destroyed, this being the limitation of the apparatus.

**860. Series-resistance multigap arresters** are built by the Westinghouse Company in recognition of this condition, called "Low-equivalent arresters." The series resistance is expected to limit the rate of discharge within safe limits. This type ordinarily uses but a single shunt resistance. There is considerable difference of opinion as to whether or not this series resistance is desirable. It sometimes saves the arrester, but at the expense of the apparatus by increasing the time necessary to relieve the system.

Digitized by Google

**861. Care of multigap arresters** requires the frequent removal of dust, best accomplished by blowing with compressed air. The arresters should be disconnected during this process.

**862. Aluminum-cell lightning arresters** depend for their action on the properties of aluminum when inserted in a suitable electrolyte, shown by Fig. 130. When an e.m.f. is applied between two electrodes, insulating films are formed which break down if the forming voltage is exceeded and reform immediately when the voltage becomes normal. This cell more nearly conforms to the ideal than any other arrester; it may be set for a very small increase in e.m.f.; its discharge rate is enormous and it immediately resumes normal condition after the discharge. Since the cells can be formed to withstand permanently only about 300 volts, a great number in series is required for high potential systems. Conical shaped aluminum electrodes are mounted on rods with spacers allowing a uniform space between (Fig. 131). Electrolyte is inserted in these spaces, great care being required to get uniform depth. The whole stack is then inserted in a tank of oil.

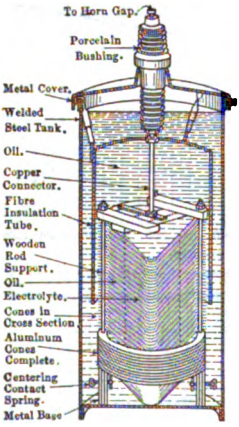

FIG. 131.—Construction of aluminum arrester.

**863. Charging aluminum arresters.** Continuous connection to the line is not possible on account of the loss of energy, and therefore horn gaps are usually connected in series. This requires frequent charging of the cells, at least daily, because the film gradually dissolves, more rapidly in warm weather.

Care of aluminum arresters requires not only this frequent charging, but also watching the charging current which is a guide to the condition of the electrolyte. Care should be exercised to prevent freezing of the electrolyte at very low temperatures, as it might destroy the arrester.

**864. Arrangement of arresters on polyphase circuits** may consist either of an arrester between each line and ground, or arresters for each line connected together on the ground side and then to ground through an additional arrester. The first method is used where the neutral of the system is grounded and the second where ungrounded.

**865. Grounds for lighting arresters** should be most carefully made. Numerous iron pipes driven several feet in the ground and interconnected by a copper strip are good. Copper plates buried deep in coke with earth filling are also used. In addition the arrester ground should be connected to the steel frame, piping, and other grounded materials in the building.

**866. Summary of uses of various types of arresters.**

(1) Spark gap—
- (a) Series resistance } D.C. systems, all voltages.
- (b) Fuse } A.C. trolleys, along the line.
- (c) Magnetic blowout
- (d) Plain—Single point on transformer secondaries.

(2) Horn gap—
- (a) Series resistance } A.C. systems, all voltages, located on poles.
- (b) Fuse } D.C. and A.C. series systems.

(3) Multipath—Frequent location along D.C. lines.

(4) Multigap—A.C. systems.
- (a) Plain—Frequent location along small distribution systems.
- (b) Series resistance—Frequent location along systems up 15,000 volts.
- (c) Shunt resistance } Station use on systems of moderate size and length of line.
- (d) Shunt and series resistance, }

Digitized by Google

(5) Aluminum cell—
(a) In small jars or tanks, { D.C. systems along the line and D.C. stations.
(b) All stacks in one tank, A.C. systems up to 7,500 volts.
(c) Separate tanks, A.C. system up to 150,000 volts.

**867. The cost of lightning arrester equipment** is about as follows. Three-phase grounded-neutral systems: Aluminum cell, $70+$10 per 1,000 volts; multigap type, $13 per 1,000 volts. Three-phase ungrounded: Aluminum cell, $100+$15 per 1,000 volts; multigap type, $15 per 1,000 volts

**868. The cost of 200-amp. choke coils** of the "hour glass" type, is about: $20+$0.50 per 1,000 volts, up to 70,000 volts; $30+$0.80 per 1,000 volts, above 70,000 volts; the increased cost per 100 amp. is about $7. Pancake-type choke coils cost about $12+$20 per 100 amp. for 2,500-volt service and $40+$40 per 100 amp. for 25,000-volt service. The cost of installation of the above can usually be covered by a 15 per cent. increase, in addition to freight.

## POWER STATION WIRING

**869. Bus bars** are made either of copper as discussed elsewhere in this section, or, in the case of high-potential stations or moderate potential in small sizes, of copper tubing, copper rods, and sometimes brass or iron pipe. Special bends and fittings are available for this pipe work. Where the current capacity is small, the physical stiffness required dictates the size of conductor. Bus bars are seldom continuously insulated. They are usually supported in the open in small low-voltage stations, and in all stations of very high voltage. Cell structures are used in stations of moderate voltage in all except relatively small stations.

**870. Switch wiring** on the board, or on the switch structure, should be stiff and well insulated for the full voltage, because the wires are particularly near together at this point. Stranded wires are seldom used except for simple layouts where accurate alignment is not necessary.

**871. Main generator and exciter wiring** should be run by the shortest possible route and provided with ample insulation, even above ordinary requirements. This wiring is not protected by automatic switches. Multiconductor cables are not recommended and alternating-current and direct-current wiring must not occupy the same duct.

**872. Instrument and control wiring** form practically the nervous system of the power plant. Great care must be used to avoid trouble and only the highest grade of insulation should be used. Iron conduit should be used for all of the wires, terminating as closely as possible to the instrument panels and to the transformers. Terminals at oil switches and instrument transformers should be most carefully protected to prevent high-tension current from reaching them during switch troubles. All instrument wiring except that in main circuit must be thoroughly grounded both at the instrument transformer and at the panel. Terminal boards on the panels are of great assistance in calibrating instruments. Alternating-current and direct-current wires should not be run together any more than can be avoided.

**873. Lightning-arrester connections** should be as simple and direct as possible in order to secure maximum protection. Disconnecting switches should always be used.

**874. The prevention of corona** on wiring of very high tension requires special care. All sharp corners on the wiring and the switching apparatus must be avoided. Also see Sec. 11.

**875. Bus and switch compartments** (Fig. 132) are made of brick, soapstone and concrete, either plain or reinforced. Openings for switch inspection, etc., are usually covered with asbestos doors conveniently hung. When brick is used for the main walls, soapstone is used for horizontal walls and lesser barriers. Concrete is frequently used throughout. Whatever the materials of construction, their insulating qualities are not depended upon, and the conductors should be supported on insulators designed for full voltage with a wide margin of safety. Wide differences in design are possible, as is indicated in the cuts, and it is seldom that the same arrangement is ever used in two stations.

Digitized by Google

**876. The cost of bus and switch structures** varies widely, from $50 per switch in small sizes to $300 per switch in large capacity switches for 15,000 volts.

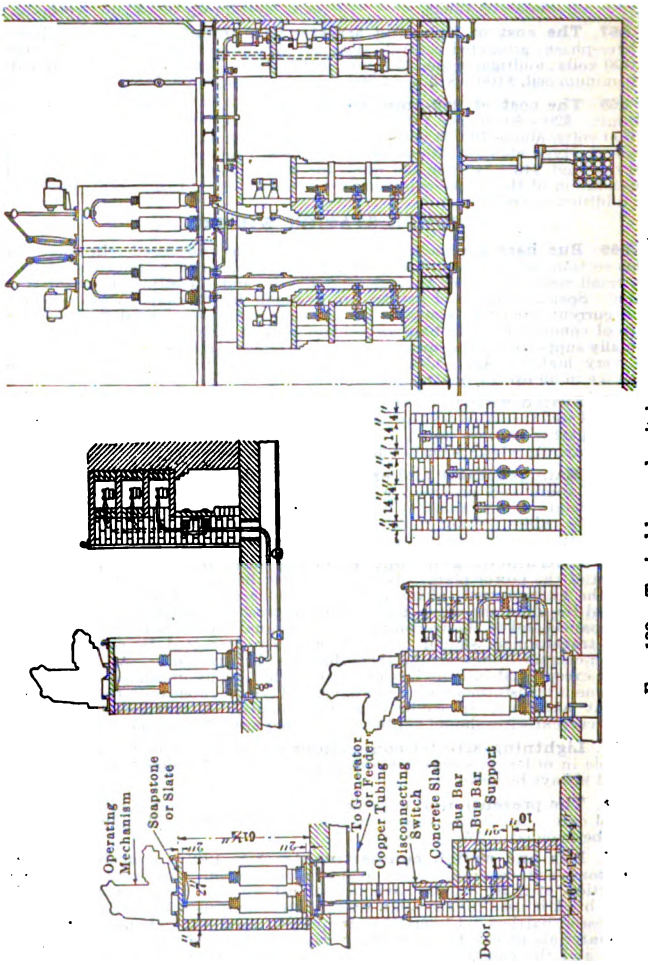

FIG. 132.—Typical bus and switch compartments.

**877. Ducts and iron conduits** are largely used in power station wiring but the latter should be avoided for alternating-current work of more than

Digitized by Google

very moderate current capacity. Clay or fibre ducts laid in concrete in the floor, or built into the ceiling cost, from 20 to 50 cents per duct ft. Iron conduit supported by clamps costs, in place, from 12 cents per ft. for the ½-in., to $1 per ft. for the 4-in. size. Brass pipe is sometimes used where large alternating currents must be carried in open conduit. The cost is about five times that of iron.

**878. Bus-bar Compartment Dimensions**

| Max. e.m.f. kv. | Bus size inches | Dimensions, inches A | B | C |
|---|---|---|---|---|
| 15 | 1–2 × ¼ | 13 | 12½ | 5½ |
| 15 | 2–2 × ¼ | 13 | 12½ | 4½ |
| 15 | 1–3 × ¼ | 13 | 12½ | 5½ |
| 15 | 2–3 × ¼ | 13 | 12½ | 4½ |
| 22 | wire | 15 | 16½ | 8½ |

| 100 | wire | 56 | 56 | 28 |

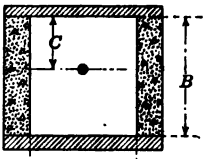

FIG. 133.

**879. Spacing of High-tension Station Wiring**

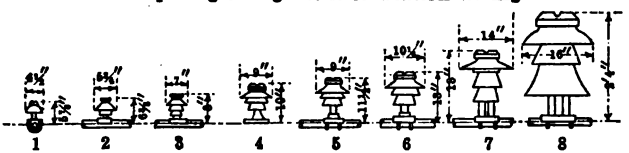

FIG. 134.

| Number ref. to cut | E.m.f., volts | Spacing, inches | Ground distance, inches | Number ref. to cut | E.m.f., volts | Spacing, inches | Ground distance, inches |
|---|---|---|---|---|---|---|---|
| 1 | 6,600 | 8 | 6 | 5 | 33,000 | 18 | 10 to 12 |
| 2 | 15,000 | 10 | 7 | 6 | 45,000 | 25 | 13 |
| 3 | 22,000 | 12 | 8 to 10 | 7 | 60,000 | 36 | 19 |
| 4 | 33,000 | 18 | 10 | 8 | 100,000 | 56 | 30 |

NOTE.—Ground distance (usually) $= \frac{\text{Wire spacing}}{2} + 1$ in.

Spacing of series transformers (self-cooled):

| | | | |
|---|---|---|---|
| 600 volts..... | 1 in. clear | 6,600 volts..... | 3 clear |
| 2,300 volts..... | 1.5 in. clear | 13,200 volts..... | 5 clear |

**880. Terminals and entrances,** particularly on high-tension overhead outlets, require the most careful design to prevent leakage during bad weather. Standard designs are on the market supplied by the various insulator companies. Wall outlets are usually relatively simple and cheap, but satisfactory roof bushings are available only at considerable expense. The latter are similar to the oil switch and transformer terminals used for outdoor work. Several types are shown in Figs. 136–138.

**881. The cost of power-station wiring** varies greatly and is exceedingly difficult to estimate. The cost of wire, supports, insulators, etc., can be obtained from manufacturers' lists, and usually an addition of from 25 per cent. to 50 per cent. will cover the cost of labor, the larger percentage being for the smaller wires. The cost of drawing into conduits varies from 1 cent to 5 cents per duct ft. The cost of joints and terminals varies

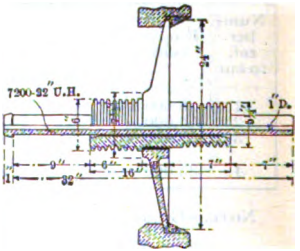

FIG. 137.—Thomas wall bushing for 66,000 volts.

between that of 5 ft. and 10 ft. of wire. The total cost of wiring varies from $0.50 to $3 per kw. of station capacity, in addition to the cost of switch gear, panels and compartments.

## MISCELLANEOUS

**882. Plant location.** Electrical considerations seldom have preponderating influence on the location or general arrangement of a power station.

Digitized by Google

The location affects the cost of the distribution system, for moderate and low voltages, directly as the square of the average distance of the load; on high-potential systems, the variation is more nearly proportional to the distance. Other conditions being equal, however, it is obvious that the best location is as near as possible to the **load-centre**.

**883. Parallel operation.** Large systems frequently require the parallel operation of power stations, and little difficulty is ordinarily experienced. In some cases where plants in close proximity are thus operated, the service conditions require that the stations shall not be automatically disconnected from each other except in case of trouble in the tie lines. In other cases provision is made for the immediate disconnection of the stations in case of trouble in either. The latter arrangement is used where there is no connection between the systems supplied by the stations, other than directly between the station bus bars. Where stations are widely separated, parallel operation is not satisfactory when the resistance drop in the connecting lines exceeds 15 per cent. on alternating-current systems and 50 per cent. on direct-current systems. The operation of such **interconnected systems** requires careful arrangement, frequently making it necessary to have a **load dispatcher** in full control of all switching operations.

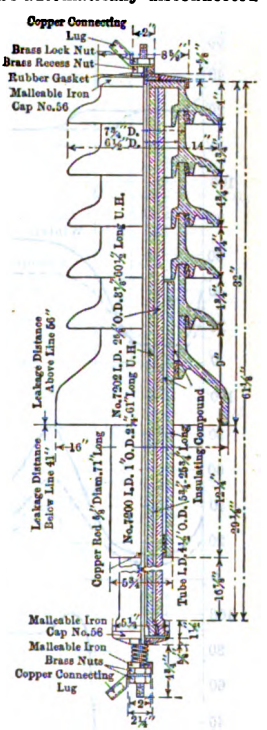

FIG. 138.—Thomas roof insulator for 66,000 volts.

## POWER-PLANT ECONOMICS

### BY GEORGE I. RHODES

**884. Load fluctuations** largely determine the desired overload capacity of units. Lighting systems have steady loads except for peaks shown by the usual load curve. Industrial loads are very steady except for certain kinds of applications to intermittent work using large units. Railway loads have considerable fluctuation even in the largest systems. Swings of five times the average are experienced when but a single car is running, twice, when about ten are running, and to 120 per cent. when a very large number are running.

**885. Sudden peaks** are always a possibility on a lighting system, and occur whenever a sudden storm appears. An increase in load of as much as 100 per cent. within a very few minutes is not uncommon.

**886. The load factor** of a machine, plant or system is the ratio of the average power to the maximum power during a certain period of time. The average power is taken over a period such as a day, or a year, and the maximum is taken over a short interval of the maximum load within that period. In each case the interval of the maximum load should be definitely specified. The proper interval is usually dependent upon local conditions and upon the purpose for which the load factor is to be determined. The yearly average of daily load factors is frequently used. (See Sec. 25.)

**887. Diversity factor** is the ratio of the sum of the maximum power demands of the subdivisions of any system or part of a system, to the maximum demand of the whole system or of the part of the system under consideration, measured at the point of supply.

**888. The load** to be carried is probably the most important factor to be

Digitized by Google

considered in power-plant design. It determines the size of plant, the kind of plant, and the size and number of units. **Typical load curves** are shown in Figs. 139 and 140. These curves are such as would be obtained from 15-min. readings of watt-hour meters but do not show the exact load on

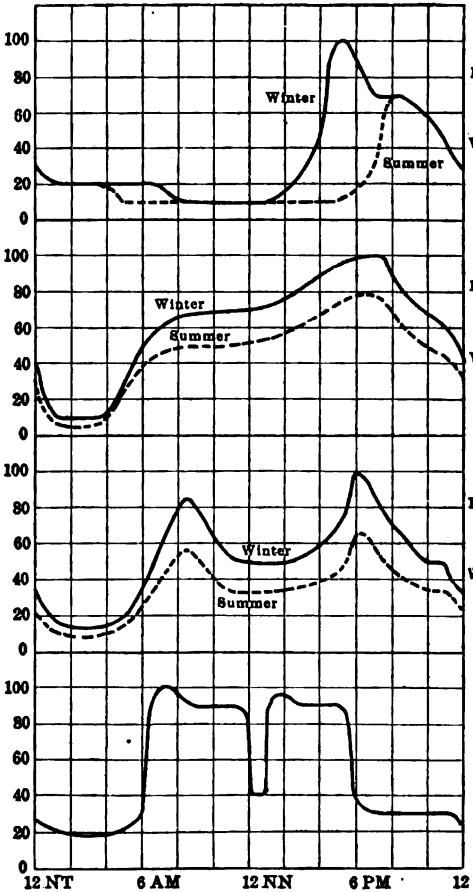

FIG. 139.—Typical load curves.

any specific plant. For typical load curves in very large central stations see *Trans.* A. I. E. E., Vol. XXXI, p. 1473, 1912.

**889. Demand factor** is the ratio of the maximum power demand of any system or part of a system to the total connected load of the system, or of the part of the system under consideration.

Digitized by Google

**890. Capacity factor** is the ratio of the average load to the total rated capacity of the equipment supplying that load. This factor is not very definite on account of variations in methods of rating apparatus.

**891. Fixed charges** as ordinarily defined with reference to power plants, are the charges necessary to carry the investment and to replace the equip-

ment when it is worn out or destroyed. Interest and taxes carry the investment, while insurance and accumulated depreciation funds cover replacement.

Digitized by Google

**892. Interest** as used in engineering computations is the annual cost of the money required for the work. It is affected by the credit of the company and the condition of general business at the time money is borrowed. If money is raised by bonds sold below par, as is frequently the case, the cost of money is not only the only interest rate on the bond, but this amount is increased in proportion to the amount the bond is sold below par and, also, by an amount which set aside annually will make up this deficit below par when the bond is retired or paid. Six per cent. should be used as an average cost of money, but it varies between 4 per cent. and 8 per cent., the lower figure for municipalities and the higher for industrial corporations.

**893. Profit on the investment,** namely, income above the total of all required expenses, interest, etc., should not ordinarily be considered in engineering work.

**894. Taxes** are proportionately more variable than interest, ranging from less than 0.5 per cent. to as high as 2.0 per cent. It is generally the case, however, that high taxes and low interest coincide, so that the probable variation of the total of interest and taxes is from 6 per cent. to 9 per cent.; 7.5 per cent. is the figure frequently used.

**895. Insurance** of power plants against fire varies from less than 0.1 per cent. for fire-proof modern plants, to as high as 1 per cent. for the old type of plant with oil-soaked wooden floors, etc. Insurance in a modern plant may seem unnecessary, but the regular visits of insurance inspectors have a beneficial influence on the operation of the plant which is frequently worth more than the cost of the insurance. The figure commonly used for the cost of insurance is 0.5 per cent.

**896. The cost of depreciation** is one of the most commonly neglected and one of the most important elements of the total cost of power. The existence of depreciation in some form is generally recognized, but it is frequently neglected in actual operation of companies, either because of lack of income or desire for immediate profit.

**897. Physical depreciation** is the result of deterioration due to wear and tear caused by regular use, decay and the action of the elements.

**899. Functional depreciation** is the result of lack of adaptation to function, caused by **obsolescence** and **inadequacy.** Obsolescence is due to changes or advances in the art which renders a piece of apparatus, or a whole class of it, obsolete and uneconomical of use, as compared with new types which have been developed at a later date and which are much more efficient (H. G. Stott, *Trans.* A. I. E. E., p. 1619, 1913).

Digitized by Google

**900. Life expectancy of equipment.** The life expectancy of power-plant equipment, taking functional depreciation into account, is as follows:*

| Property | Total life (years) | Scrap value, per cent. of original cost |
|---|---|---|
| Buildings | 75 | 5 |
| Boilers, stokers and furnaces | 20 | 5 |
| Conveyers, elevators and hoists | 20 | 1 |
| Turbines, complete | 12 | 10 |
| Engines and condensers | 12 | 10 |
| Piping, values and traps | 12 | 3 |
| Pumps | 12 | 5 |
| Synchronous converters, transformers and exciters, etc. | 20 | 10 |
| Switching apparatus and instruments | 12 | 5 |
| Alternators | 12 | 10 |
| Motors | 20 | 10 |
| Tools and sundries | 10 | 3 |
| Storage batteries | 10 | 10 |

**901. Scrap value.** It is obvious that in computing the net annual amount of depreciation the scrap value of the apparatus must be deducted from the original or first cost.

**902. Methods of caring for depreciation. Charging to repairs all replacement** of apparatus, either in part or as a whole, is expected in many companies to care for depreciation. Ordinary repairs will not prevent a machine from finally reaching a point, due to wear and tear, where it will have to be replaced and in small companies this replacement would cost such a large proportion of the total investment that it is desirable to accumulate a fund for the purpose. If replacements are charged to repairs this item will become irregular in amount, which is a very undesirable condition. In very large companies the irregularity becomes less and consequently the method can be used with success.

**903. The straight-line method of computing depreciation** is based on the assumption of a uniform reduction in value. It is commonly assumed that the accumulated depreciation fund, under this method, bears no interest, but such is not necessarily the case. The method has the great advantage of being very simple in application.

**904. The amortization or sinking fund method of computing depreciation** assumes that the accumulated depreciation fund is invested and bears interest. The effect is to make the annual rate less, of course, than it would be if the fund bore no interest. This method is not easy of application to actual conditions. Some authorities consider that it represents, more nearly than the straight-line method, the depreciation in actual value of the property as determined by what a purchaser could afford to pay for it.

**905. Calculations of depreciation,** by whatever method, should be made separately for each type of equipment, taking into account its expected life and its scrap value. There is much chance for error in deciding on a percentage to apply to an entire property, and if used it should be determined from a detailed calculation. It is evidently subject to some variation from time to time as new equipment is added.

**906. Obsolescence** is commonly regarded as a type of depreciation to be charged to the cost of power. This is not necessarily the case. Obsolescence does not accrue from day to day, like physical depreciation, but accrues coincidently with advances in the art resulting in new and more efficient machinery or methods. The full physical life of equipment is possible in any event, whether or not obsolescence occurs, and the question whether a piece of equipment should be replaced before it wears out is determinable by equating the saving in operating expenses against increased

* Stott, H. G., "Power Costs"; *Trans.* A. I. E. E., 1913, Vol. XXXII, p. 1112.

Digitized by Google

fixed charges. In comparing different types of plants it is misleading to consider obsolescence as different for the various types.

Physical and functional depreciation costs must not be added. If functional depreciation will shorten the expected life the proper rate to care for this shortened life should be used, which includes physical depreciation. Eminent engineers have incorrectly allowed a percentage for physical depreciation and an additional percentage for functional depreciation.

### 907. Summary of H. G. Stott's Classification of Operating and Maintenance Costs

(Material and labor separated for each item)

| Production costs | Production repairs costs |
|---|---|
| Management and care | Furnaces and boilers |
| Boiler room | Boiler accessories |
| Engine room | Engines |
| Electrical | Engine accessories |
| Fuel for steam | Piping |
| Water for steam | Electric generators |
| Lubricants | Electrical accessories |
| Supplies | Tools |
| Station expense | Building |
| General | General |

**908. Power cost data** given in this section of the handbook represent as nearly as possible the **present state of the art** rather than old information. For instance, a great deal of data are available in reports to the various public service commissions which gives costs far in excess of these indicated here. In almost every instance the reporting companies operated plants which contain a great deal of inefficient apparatus maintained at great expense, but for less cost than the fixed charges of new apparatus. Companies operating modern plants also frequently operate old plants, but do not report them separately. While these reports give valuable data as to what is being done under old designs, they are of little use for the purpose of estimating costs in truly modern plants.

### 909. Boiler Room Equipment Costs per Rated Boiler Horse-power using Coal for Fuel*

| | Dollars per h.p. | |
|---|---|---|
| | High | Low |
| Boilers exclusive of masonry setting | $11.00 | $8.00 |
| Superheaters | 3.00 | 0 |
| Stokers | 5.50 | 3.00 |
| Masonry settings for boilers | 3.50 | 2.00 |
| Flues | 1.50 | 0.75 |
| Stacks | 4.00 | 2.00 |
| Economisers | 4.00 | 0 |
| Mechanical draft | 3.00 | 0 |
| Feed pumps | 1.50 | 0.60 |
| Feed heaters | 1.00 | 0.40 |
| All piping and pipe covering | 10.00 | 6.00 |
| Coal chutes and ash hoppers | 1.25 | 0 |
| Various, such as indicating and recording devices, damper regulator, ladders and runways, painting, etc., etc | 1.00 | 0.50 |
| Totals | $50.25 | $23.15 |

| 42. Engineering expenses and inspection | 4.00 | 6.00 |

### 914. Analysis of the Average Losses in the Conversion of 1 Lb. of Coal Containing 12,500 B.t.u. into Electricity. Producer Gas Engine Plant†

| | B.t.u. | Per cent. |
|---|---|---|
| 1. Loss in gas producer and auxiliaries | 2,500 | 20.0 |
| 2. Loss in cooling water in jackets | 2,375 | 19.0 |
| 3. Loss in exhaust gases | 3,750 | 30.0 |
| 4. Loss in engine friction | 813 | 6.5 |
| 5. Loss in electric generator | 62 | 0.5 |
| 6. Total losses | 9,500 | 76.0 |
| 7. Converted into electrical energy | 3,000 | 24.0 |
| | 12,500 | 100.0 |

| 3,000 | 145,500 | 202,000 | ..... | 48.50 | 67.35 | ..... |

(a) Includes producer, engine, electric generator, piping, switchboard and auxiliaries, all erected with suitable foundations.

**920. Influence of load factor on cost of power.**
(a) **Fixed charges.** It is obvious that this cost varies inversely as the load factor. It is important, however, that the proper factor be used, namely the annual capacity factor of the total equipment installed.
(b) **Operating labor.** It is obvious that in small plants, or plants of very few units, a large amount of labor is unaffected by the load on the

Digitized by Google

plant. As the number of units increases, this portion becomes relatively smaller. It is probable that the ratio of full-load labor costs per hour to no-load costs varies from 2 to 1 in plants of a single unit, to 5 to 1 in plants of a large number of units.

(c) **The coal** required to maintain a plant ready for instant service with one unit running at no-load, consists of that required for its no-load steam, that of the auxiliaries and that for banked fires under sufficient boiler capacity to carry the peak load. This total no-load coal ranges from 25 per cent. of full-load coal in a plant of one unit to 8 per cent. in a plant of many units.

(d) **Operating repairs** and other expenses are very indefinite and uncertain except over a long period of time, but probably vary in direct proportion to the load, thus being independent of the load factor.

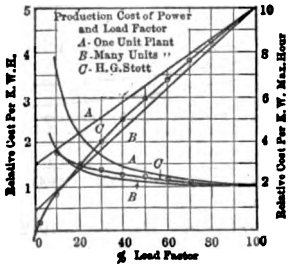

FIG. 142.—Variation in cost of power with load factor.

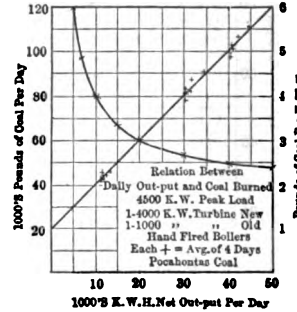

1000'S Pounds of Coal Per Day
Pounds of Coal Per K.W.H.
Relation Between Daily Out-put and Coal Burned
4500 K.W. Peak Load
1-4000 K.W. Turbine New
1-1000 " " Old
Hand Fired Boilers
Each + = Avg. of 4 Days
Pocahontas Coal
1000'S K.W.H. Net Out-put Per Day

FIG. 143.—Variation in coal consumption with load factor.

(e) **Total production cost** at no-load varies from 30 per cent. of that at full load in plants of a single unit, to 10 per cent. in plants having many units. Mr. H. G. Stott has found that experience shows a variation in cost per kw.-hr. inversely as the fourth root of the load factors. Curves showing these costs are given in Figs. 142 and 143.

(f) **Period of load factor.** Since the no-load costs in a station are determined largely by the peak load expected during the month or week, it is evident that load factors for a shorter period than a year are advisable. Possibly the average daily or weekly load factor will give the best method of comparing these costs.

**921. Comparison of power costs in different plants** will lead to unreliable results unless certain fundamental conditions are taken into account. The chief of these are:

(a) **Certainty that costs include the same items** for each plant. Management, general expenses and building repairs are frequently omitted and care must be exercised to ascertain just what makes up the total cost. Hence the necessity of standard methods of cost accounting.

(b) **Load factors** if different require reductions of costs to the same basis. Fixed charges are inversely as the first power, and operating costs inversely as the fourth root of the load factors. Variations from 20 per cent. to 60 per cent. can be compared closely by this method.

(c) **Coal costs must** be compared on some common basis such as the cost per 1,000,000 B.t.u. available after deducting the B.t.u. in the ash.

(d) **Labor costs** must be treated similarly on the basis of the average wage per hour per man.

(e) **Fixed charges** must be on the same basis, not necessarily with the same life of equipment, but with the same method of figuring depreciation costs. It is also important to know how much spare apparatus is being maintained and whether or not the plant is complete, or one in which there is room for considerable additional apparatus.

**922. Example of comparison of power costs.*** Let $C_1$, $C_2$ = total cost per kw-hr. in plants 1 and 2,
$I_1$, $I_2$ = fixed charges per kw-hr. in plants 1 and 2,
$F_1$, $F_2$ = fuel costs per kw-hr. in plants 1 and 2,
$L_1$, $L_2$ = labor costs per kw-hr. in plants 1 and 2,
$O_1$, $O_2$ = total other costs per kw-hr. in plants 1 and 2,
$f_1$, $f_2$ = cost per 1,000,000 B.t.u. in plants 1 and 2,
$l_1$, $l_2$ = average hourly wage in plants 1 and 2,
$R_1$, $R_2$ = average daily load factors in plants 1 and 2.
$C_2'$ = total cost in plant 2 reduced to plant 1 conditions.

Example:

| | |
|---|---|
| $C_1 = 6.5$ mills per kw-hr. | $C_2 = 7.5$ mills per kw-hr. |
| $I_1 = 2.0$ mills per kw-hr. | $I_2 = 2.5$ mills per kw-hr. |
| $F_1 = 3.0$ mills per kw-hr. | $F_2 = 3.0$ mills per kw-hr. |
| $L_1 = 1.0$ mills per kw-hr. | $L_2 = 1.5$ mills per kw-hr. |
| $O_1 = 0.5$ mills per kw-hr. | $O_2 = 0.5$ mills per kw-hr. |
| $f_1 = 10$ cents per 1,000,000 B.t.u. | $f_2 = 8$ cents per 1,000,000 B.t.u. |
| $l_1 = 30$ cents per hour | $l_2 = 40$ cents per hour |
| $R = 50$ per cent. | $R = 40$ per cent. |

$$C_2' = I_2\frac{R_2}{R_1} + \left[F_2\frac{f_1}{f_2} + L_2\frac{l_1}{l_2} + O_2\right]\left[\frac{R_2}{R_1}\right]^{\frac{1}{4}} = 2.5\times\frac{40}{50} + \left[3.0\times\frac{10}{8} + 1.5\times\frac{30}{40} + 0.5\right]\left[\frac{40}{50}\right]^{\frac{1}{4}}$$

$$= 2.0 + [3.75 + 1.125 + 0.5]\,[0.945] = 7.08 \text{ mills per kw-hr.}$$

That is, if the second plant were operated under the same labor and fuel cost and the same load factor as the first plant, it would cost 7.08 mills per kw-hr., as against 6.5 mills; this is less efficient operation, but not as bad as indicated by the uncorrected figures. The correction for fixed charges should more properly have been made on the basis of annual load factors.

**923. Suitability of different types of power plants.** Steam-electric plants are most suitable under conditions of moderate or low load factor and fuel costs. Gas-driven and hydraulic-electric plants are suitable only with high load factors and fuel costs.

**The steam-engine-driven plant** is suitable only in small sizes or where it is necessary to run non-condensing, under which conditions it is more economical than the turbine. It is more expensive in first cost in all sizes.

The **steam-turbine-driven plant** is of general adaptability to all sizes and loads with the above exceptions.

The **low-pressure turbine** offers a very satisfactory and most economical method of extending existing engine-driven plants with economy equal to best modern practice. It has little advantage for new plants, however.

**Gas-engine driven-plants** are most suitable in small sizes where first cost is not greatly in excess of that of steam plants, and where the difference in economy is much greater. Larger sizes have excessive investment costs and expensive maintenance which are balanced by fuel saving only with high load factors and steady load.

**Hydraulic plants** are suitable when there is a use or market for a seasonal delivery of power at high load factor. Very few plants, except at Niagara, have a summer output in excess of 25 per cent. of rating.

**924. Modern tendencies in power-plant design** point to inexpensive plants of high operating economy. Expense of construction is reduced by simplicity in design, using few large units; reliability is secured by the use of the highest quality of materials and apparatus rather than by duplication, with its attendant complication. Operating economy is secured through better control of combustion, the use of highly efficient apparatus whose efficiency adds relatively little to the cost of the entire plant, and the attendant reduction in labor cost through the simplicity of the plant and the small number of operating units. The development of stokers allowing very high rates of evaporation in the boilers with high economy, has reduced the investment costs in boiler equipment and building and also improved operating economy by reducing the amount of coal consumed in banked fires. There is a strong tendency toward compactness of layout, allowing only

* Adapted from Stott, H. G., Gorsuch, W. S., *Trans.* A. I. I. E.

Digitized by Google

sufficient floor space for the dismantling of apparatus during repair. The perfection of the mechanical design of turbo-generators permits the use of skeleton foundations in which the condenser can be placed with great space economy. The electrical switching equipment still has a tendency toward expensive complication, which the writer believes will gradually give way to simplicity and ruggedness, except in the largest plants.

**925. Improvement of economy of existing plants** requires, first of all, an accurate knowledge of all the elements entering into the cost in that particular plant, and then a gradual elimination of the elements producing inefficiency.

**926. Boiler-room practice** affords probably the most fruitful field for improvement, as it has hitherto been the most neglected. Numerous instruments, meters and devices are on the market which make possible a continual check on the efficiency of the boiler room. It is not only possible to know the overall efficiency, but to determine readily just what are the causes of inefficiency; there are automatic devices, also, which remove some of these causes. A careful study should be made as to the variation in efficiency with peak load and load factor, so that the inherent improvement in economy with good load factor shall not be mistaken for the results of better operation. Determinations should be made as to the proper number of boilers to use, the relation between active fire hours and banked fire hours, and just when it is profitable to let the fires go out. It is highly important that the boilers themselves be kept clean both inside and out; means are available to facilitate this work, both chemical and mechanical. The firemen should be carefully instructed in proper methods of firing and closely watched to see that they follow instructions.

**927. Engine or turbine room operation** offers a less fruitful field for improvement since the inherent economy of the units, more particularly of the turbines, is less under the control of the operators. With engines, however, it is highly important that valve settings be maintained properly. The proper loading of units has some influence on economy. The balance of exhaust steam produced and that needed for feed-water heating is particularly important at light loads, when ordinarily there is an excess of steam which is wholly wasted. Electric drive of some of the auxiliaries frequently serves as a corrective. Air leakage into the condenser is an important source of loss.

**928. Electrical operation** offers a relatively limited field for improvement in economy. It is frequently possible, however, by rearranging the ventilation of windings and keeping them properly clean, to carry a better average load on the prime movers, which adds to the economy and also to the effective size of the station.

**929. Labor shifts.** Labor costs can frequently be reduced by arranging overlapping shifts, thus providing the necessary men during peak loads, without unnecessary men before and after. The efficiency of labor should be measured not alone by its cost per kw-hr., but by the cost per unit of work performed.

**930. Repairs** should be made as soon as their necessity is discovered. A high grade of maintenance is usually cheaper than lax maintenance, and increases the effective life of the apparatus.

**931. Economy in supplies** does not mean cheap materials, but the choice of those best adapted to the work and which give the lowest total cost for the object accomplished.

## POWER TRANSMISSION

### TRANSMISSION SYSTEMS

**1. Systems in common use.** There are three systems in common use to-day: the direct-current (Thury) system, abroad only; the single-phase system, in railway work; and the three-phase system, for general transmission. These systems may be compared as follows, in terms of effective current and voltage.

| | |
|---|---|

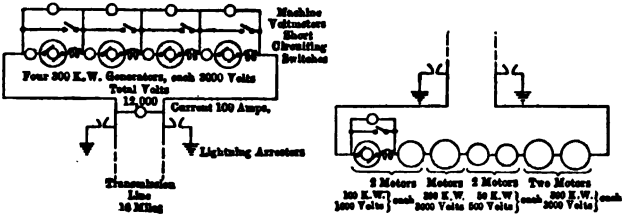
giving satisfactory service (Fig. 1). The required line voltage is obtained by connecting series-wound generators, in series, the voltage per commutator ranging from 1,300 to 4,000 volts. Each generator is mounted on an insulated platform and connected to its prime mover by an insulated coupling. When not in use, the generator is short-circuited. In this system the current is maintained constant by automatic devices which control the prime-mover speed, shift the brushes, and shunt the field, and the voltage is made to vary with the load. The power is delivered to motors similar in construction to the generators. The motor speed is controlled by shifting the brushes, and simultaneously shunting the field. Line voltages approximating 70,000 volts are in use, and a transmission distance of 112 miles (Moutier-Lyons) has been reached.



Machine Voltmeters
Short Circuiting Switches
Four 300 K.W. Generators, each 2000 Volts
Total Volts 12,000
Current 100 Amps.
Lightning Arresters
Transmission Line 16 Miles
2 Motors 100 K.W. each 1000 Volts
Motors 200 K.W. each 2000 Volts
2 Motors 50 K.W. each 500 Volts
Two Motors 300 K.W. each 3000 Volts

FIG. 1.—Typical Thury system.

**4. Advantages claimed for Thury system:** (a) power-factor always unity; (b) higher effective pressures for the same line insulation (tests by Thury indicate that with given line insulation, direct current may be twice the alternating current voltage). The maximum pressure occurs only during maximum loads; (c) no dielectric losses; (d) two wires only to be insulated; (e) underground single-conductor cable can be obtained for 60,000 volts, and with grounded neutral, the line pressure would be 120,000 volts; (f) no inductance or capacity troubles such as surges and abnormal voltage rises; (g) a number of stations can be operated in series and a station can be connected to the line at any point; (h) switching arrangements very simple; (i) in hydraulic stations under variable head, greater efficiency can be obtained since constant speed is unnecessary; (j) adapted for industrial work requiring constant torque; (k) line repairs can be easily and safely made while the line is in operation after grounding the conductor at the point in question (not applicable to systems with grounded neutral).

**5. Disadvantages of Thury system:** (a) insulated floors and couplings; (b) generating units must necessarily be of moderate capacity, though several generators may be connected to one prime mover; (c) the line loss is constant and independent of the load, although the current may be somewhat decreased on light loads; (d) constant-head water-wheel not ideal for constant current (variable speed); (e) special regulating devices required on motors; (f) impossibility of securing overload torque on the motors, even for a short period; (g) greater liability of damage to generators, due to lightning, and hence more expensive protective devices are required.

**6. Single-phase systems,** except in occasional railway installations, are little used in transmitting large amounts of energy for great distances, since for a given voltage between lines, the copper efficiency is 75 per cent. of that of the three-phase system. For power purposes the single-phase motor is less satisfactory than the polyphase motor. The output of a given single-phase generator is less than when polyphase wound.

**7. Three-phase systems.** Three-phase transmission and distribution are superseding the other systems, due to greater copper efficiency, the balanced condition of voltage (even under unbalanced loads) and the smaller number of conductors required in comparison with the two-phase system. The great flexibility of the three-phase system, and its advantages with respect to the use of both induction and synchronous machinery, are also important considerations in its favor.

## ELECTRICAL CALCULATIONS

**8. The required size of conductor for a direct-current line** may be readily estimated. With a given power, $P$, to be delivered at voltage, $E$, the value of current, $I$, is determined from the relation:

$$I = \frac{P}{E} \qquad \text{(amp.)} \qquad (1)$$

One mil-foot of copper has a resistance of about 10 ohms at 15 deg. cent. (62 deg. fahr.). If the conductor is operated at a normal current density of 0.001 amp. per cir. mil, the drop per ft. will be 0.01 volt, regardless of the size of conductor.

**9. The total voltage drop** may be expressed:

$$e = 0.01 \times l \qquad \text{(volts)} \qquad (2)$$

where $l$ is the total length of conductor in ft. If the current density is different from this normal value, $e$ will be in direct proportion to the current density. Thus, if the density is 1 amp. per 1,200 cir. mils, and $l = 100{,}000$ ft., then $e = 0.01 \times 100{,}000\ (1{,}000/1{,}200) = 833$ volts.

**10. Efficiency of transmission** may be expressed:

$$\eta = \frac{E}{E+e}\,100 \qquad \text{(per cent.)} \qquad (3)$$

If the receiver voltage in the above case were 10,500, then $\eta = 10{,}500/(10{,}500+833)$ or 92.6 per cent.

Power lost per mil-foot of copper at the normal density is represented by the expression:

$$I^2r = (10^{-3})^2\,10 = 10^{-6} \qquad \text{(watts)} \qquad (4)$$

Total power lost at the normal density is

$$I^2R = 10^{-6} \times c.m. \times l \qquad \text{(watts)} \qquad (5)$$

where $c.m.$ is the conductor cross-section in cir. mils, and $l$ is the total length of conductor in ft. If the current density differs from the normal, the right-hand side of Eq. 5 must be multiplied by the square of the ratio of the densities. Constant current high-voltage systems are usually so designed that the line losses are kept within prescribed limits.

**11. Example of design.** Required to transmit 2,000 kw. 15 miles, with 10 per cent. line loss.

It is customary to allow 1,000 volts per transmission mile, but this may be modified somewhat by considerations of line cost. Assuming a pressure at the receiver of 15,000 volts. $I = 2{,}000{,}000/15{,}000 = 133$ amp. The permissible voltage drop = 1,500. Let $e'$ = voltage drop at normal current density; then $e' = 0.01 \times 30 \times 5{,}280 = 1{,}584$ volts at normal density. Actual density must be $\frac{1{,}500}{1{,}584}$ amperes per 1,000 cir. mils. Hence the cir. mils required are

$$133 \times \frac{1{,}584}{1{,}500} \times 1{,}000 = 140{,}000.$$

**12. The regulation and efficiency of a single-phase or a symmetrical polyphase system** may be calculated by considering one conductor only, assuming a neutral which has zero resistance and zero reactance, as the return wire. A three-phase system may also be treated as a single-phase system transmitting one-half the power.

**13. Alternating-current transmission-line calculations.** A single-phase or symmetrical polyphase system having resistance per wire $R$ ohms and reactance per wire $X$ ohms and a load current to neutral of $I$ (amp.) at power-factor, $\cos\theta$, is represented in Fig. 2 and the voltage relations are shown vectorially in Fig. 3. The electrostatic capacity is assumed negligible.

Knowing the receiver voltage, $E_r$, the generator voltage, $E_g$, may be readily calculated.

$$E_g = \sqrt{(E_r\cos\theta + IR)^2 + (E_r\sin\theta + IX)^2} \qquad (6)$$

$$\text{Per cent. regulation} = \frac{E_g - E_r}{E_r}\,100 \qquad (7)$$

$$\text{Efficiency} = \frac{E_r I\cos\theta}{E_r I\cos\theta + I^2R} \qquad (8)$$

Digitized by Google

If $E_g$ is fixed and it is desired to determine $E_r$ (6) may be used, but a cumbersome quadratic equation as a rule results. For practical work, the regulation may be assumed, the value of $E_r$ determined from (7) and substituted in (6). If the calculated regulation then differs materially from that assumed, another trial may be necessary. If the receiver rather than the generator voltage be fixed, the problem is much simplified.

**14. Example of single-phase calculation.** Transmission distance, 20 miles; generating voltage, 33,000 volts; frequency, 60 cycles per sec., full-load power-factor, 85 per cent., spacing of wires, 48 in.; permissible line loss, 10 per cent. of power generated.

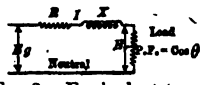

FIG. 2.—Equivalent transmission line to neutral.

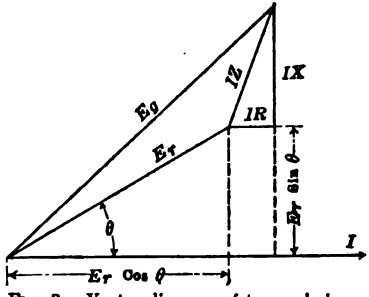

FIG. 3.—Vector diagram of transmission line.

Assumed power at receiver = 5,000 kw. Assuming 15 per cent. regulation, the e.m.f. at the receiver equals 28,700 volts, and the voltage from wire to neutral at the receiver is 14,350 volts. Current per wire = 5,000,000/(28,700 × 0.85) = 205 amp. Loss per wire = (0.10/0.90) × (5,000/2) = 278 kw. Resistance per wire = 278,000/(205)² = 6.61 ohms. Resistance per mile = 6.61/20 = 0.331 ohms.

From the table of Par. **38** the nearest size of wire is No. 000 A.W.G. copper having 0.336 ohms per mile or a total resistance (20 miles) of 6.72 ohms.

Reactance per mile (Par. **40**) of single conductor, 0.692 ohms. Total reactance, 13.84 ohms. Substituting in (6)

$$E_g = \sqrt{[(14{,}350 \times 0.85) + (205 \times 6.72)]^2 + [(14{,}350 \times 0.527) + (205 \times 13.84)]^2} = 17{,}070 \text{ volts.}$$

$$\text{Regulation} = \frac{17{,}070 - 14{,}350}{14{,}350} 100 = 18.95 \text{ per cent.}$$

The calculation shows material error. Assume 19 per cent. regulation, and

$$E_g = \sqrt{[(13{,}870 \times 0.85) + (212 \times 6.72)]^2 + [(13{,}870 \times 0.527) + (212 \times 13.84)]^2} = 16{,}690 \text{ volts.}$$

The calculated regulation is then $\frac{16{,}690 - 13{,}870}{13{,}870} 100 = 20.3$ per cent. As this checks closely with the 19 per cent. regulation assumed, another trial is unnecessary, unless greater refinement is desired.

The efficiency then becomes $\eta = 2{,}500/[2{,}500 + (205)^2 6.72]$ or 90 per cent.

With aluminum as the conductor, the reactance drop would be slightly less.

**15. Example of three-phase calculation** of a line having the same constants as are given in Par. **14**. Transmission distance, 20 miles; generating station line voltage, 33,000 volts; frequency, 60 cycles; load power-factor, 85 per cent.; spacing of wires, 48 in.; permissible line loss, 10 per cent. of power generated; power at receiver, 5,000 kw.; voltage to neutral, generating station 33,000/$\sqrt{3}$ = 19,050 volts. Assuming 15 per cent. regulation, voltage at receiving station = 19,050/1.15 = 16,570 volts. Current per wire = 5,000,000/(3 × 16,570 × 0.850) = 118.4 amp. Loss per wire, to neutral = $\frac{5{,}000}{3} \times \frac{0.10}{0.90}$ = 185 kw. Resistance per wire = 185,000/(118.4)² = 13.20 ohms. Resistance per mile = 13.20/20 = 0.660 ohms.

Digitized by Google

From Par. 38 the nearest wire size is No. 1 A.W.G. which has a resistance of 0.672 ohms per mile.

Total resistance = $20 \times 0.672 = 13.44$ ohms.
Reactance per mile (Table 40) ..... 0.734 ohms.
Total reactance ..... 14.68 ohms.
Substituting in (6)

$$E_g = \sqrt{[(16{,}570 \times 0.85) + (118.4 \times 13.44)]^2 + [(16{,}570 \times 0.527) + (118.4 \times 14.68)]} = 18{,}840 \text{ volts.}$$

$$\text{Regulation} = \frac{18{,}840 - 16{,}570}{16{,}570} 100 \text{ or } 13.70 \text{ per cent.}$$

This checks well enough with the 15 per cent. regulation assumed.
Efficiency

$$\eta = \frac{1{,}667{,}000}{1{,}667{,}000 + (118.4)^2 13.44} = 1{,}667{,}000/1{,}855{,}000 \text{ or } 90 \text{ per cent.}$$

**16. Use of complex quantity.** Analytical solutions of problems involving vector quantities may be made by resolving each vector into two components, one along a horizontal or $X$ axis, called the axis of reals, and the other along the vertical, or $Y$ axis, called the axis of imaginaries. The latter component is preceded by $j = (\sqrt{-1})$ with + or − sign according to whether it leads or lags with respect to the positive real component, lag being measured in a clockwise direction.

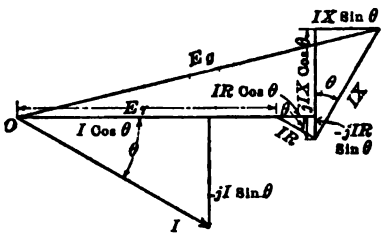

FIG. 4.—Vector diagram of transmission line using complex quantities.

Fig. 3 may be treated by this method. Referring to Fig. 4, each quantity may be resolved along $E_r$.

$$E_g = e + je' = E_r + I(\cos\theta - j\sin\theta)(R + jX) \qquad (9)$$

Each quantity represented in Fig. 4 is obtained by performing the multiplication in (9). (The effect of each component of current is treated as if the other did not exist.)

**17. Example of analytical solution of three-phase line using complex quantity.** Consider the problem of Par. 15.
Here $E_g = 16{,}570 + 118.4(0.850 - j0.527)(13.44 + j14.68) = 16{,}570 + 1{,}354 + j1479 - j840.0 + 917 = 18{,}840 + j639$. Hence $E_g = \sqrt{18{,}840^2 + 639^2} = 18{,}840$

$$\text{Regulation} = \frac{18{,}840 - 16{,}570}{16{,}570} 100 = 13.70 \text{ per cent., as before.}$$

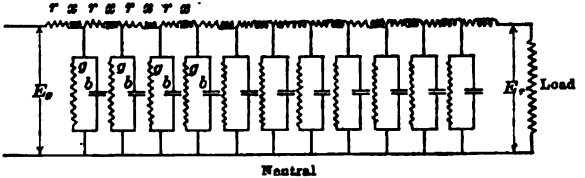

FIG. 5.—Equivalent transmission line showing capacity and leakage.

**18. Line capacity** has negligible effect on short or low-voltage lines, and, for such lines, may be neglected. On the longer lines of higher voltage the line charging current has a marked influence on the line regulation, and hence must be considered in the design of the line.

Digitized by Google

**19. A transmission line** may be represented by a single conductor having a uniform linear resistance ($R=r+r+r$) and reactance ($X=x+x+x$), and an infinite number of leaks ($g$, $g$, $g$,) and condensers or capacity susceptances ($b$, $b$, $b$,) in parallel between the line and neutral (see Fig. 5). The exact analytical treatment of such a line is rather complicated, and for practical purposes the line capacity may be considered as concentrated at the centre of the line (Fig. 6), or in two condensers, each of one-half this capacity and placed at opposite ends of the line (Fig. 7). The former is termed a nominal $T$* and the latter a nominal $\pi$,* or a split condenser. In the former case the entire charging current flows over half the line and in the latter case one-half the charging current flows over the entire line. The leakage current can usually be neglected. Where the corona and insulator losses are not negligible their effect may be included. If the transformers are to be included with the line, their equivalent single-phase resistance and leakage reactance must be added to the line resistance and reactance respectively; the energy component of the no-load current must be added to the line-leakage current and the quadrature component or magnetising current must be subtracted from the line-charging current.

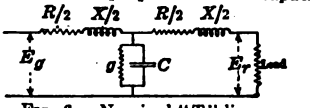

FIG. 6.—Nominal "T" line.

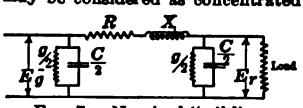

FIG. 7.—Nominal "π" line.

**20. Voltage distribution.** The true voltage distribution and the approximate voltage distribution for a 150-mile, 150,000-volt line are shown in Fig. 8. It will be noticed that the difference is very slight, especially near the ends.

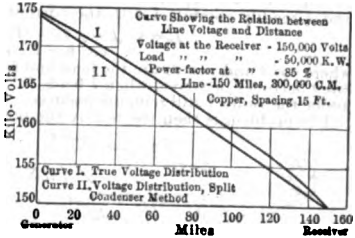

FIG. 8.—Voltage drop in line.

**21. The charging current** for a given voltage, $E_c$, is

$$I_c = 2\pi f E_c C \qquad \text{(amp.)} \qquad (10)$$

where $f$ is the frequency in cycles per sec., $E_c$ the pressure across the condenser terminals in volts, and $C$ the condenser capacity in farads. The values of $I_c$ for different spacing and sizes of conductor are given in Par. 42, 43.

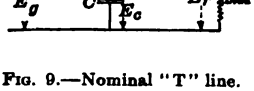

FIG. 9.—Nominal "T" line.

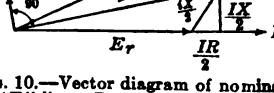

FIG. 10.—Vector diagram of nominal "T" line. Power-factor = 1.0.

**22. A nominal "T" line** is shown in Fig. 9, and Fig. 10 shows the vector relations in the circuit for unity power-factor load. Fig. 11 gives the vector diagram when the load current lags by an angle $\theta$ with respect to the load voltage. It will be observed that the condenser charging current is in quadrature with and leading the voltage $E_c$, consequently the $IR$ drop leads $E_c$ by 90 deg. and $iX$ leads $E_c$ 180 deg. It will also be noted that $E_c$ is at some potential between $E_g$ and $E_r$, but for practical considerations, $E_c$ is assumed equal to $E_r$, and no appreciable error results. In fact, the cal-

* See Bibliography 16.

Digitized by Google

culated charging current may be in error many times this amount, due to the fact that the e.m.f. wave of the alternator may differ appreciably from a sine-wave. This last factor should be carefully investigated if a high degree of accuracy is desired. It is evident, from inspection, that Figs. 10 and 11 are not capable of simple geometrical solution.

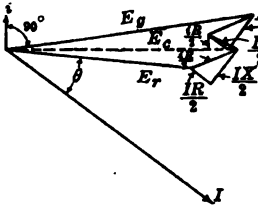

FIG. 11.—Vector diagram of nominal "T" line. Power-factor = cos $\theta$.

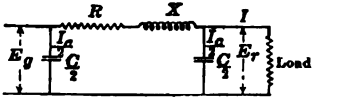

FIG. 12.—Nominal "$\pi$" line.

**23. A nominal $\pi$ line** is shown in Fig. 12, and the vector diagram is shown in Fig. 13. The condenser current $I_c/2$ leads $E_r$ by an angle of 90 deg., and is readily combined with the current $I$ to form the total current $I_o$.

$$I_o = \sqrt{(I\cos\theta)^2 + (I\sin\theta - I_c/2)^2} \quad (11)$$

$$\cos\theta_o = I\cos\theta/I_o \quad (12)$$

where $\cos\theta$ and $\cos\theta_o$ are the load and resultant power-factors, respectively. $\sin\theta$ becomes negative, when $I$ leads $E_r$, but the square of the second term under the radical still remains positive.

The problem is then treated by the method employed in Par. 12 to 17.

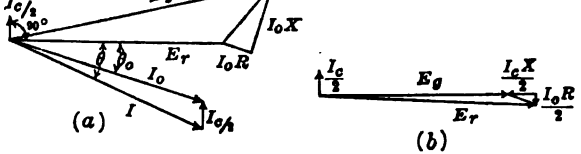

FIG. 13.—Vector diagram showing effect of line charging current.

**24. Example of calculation of a three-phase system with capacity considered.** Power to be transmitted, 50,000 kw. Substation e.m.f., 140,000 volts. Distance, 120 miles. Frequency, 60 cycles. Full-load power-factor, 90 per cent. Spacing of wires, 168 in. Allowable power loss in line, 10 per cent. of power at receiver. Power lost in each wire = 5,000,000/3 = 1,667,000 watts. Voltage to neutral (receiver) = 140,000/$\sqrt{3}$ = 80,830. Load current per wire = $\frac{50{,}000{,}000}{3\times 80{,}830\times 0.90}$ = 229.2 amp. Resistance per wire = 1,667,000/(229.2)$^2$ = 31.75 ohms. Resistance per mile = 31.75/120 = 0.2646 ohms.

From Table 38, 0000 copper or 336,420 cir. mil. aluminum have the nearest resistance, 0.2667 ohm per mile. The total resistance is 0.2667 $\times$ 120 = 32 ohms. From Table 41, by interpolation, the reactance per mile of wire = 0.795 ohm. Total reactance = 0.795 $\times$ 120 = 95.40 ohms. From Table 43 the charging current per mile per 100,000 volts is found to be 0.541 amp. Total charging current = $\frac{80{,}830\times 0.541\times 120}{100{,}000}$ = 52.47 amp. Charging current at the end of the line $I_c/2$ = 52.47/2 = 26.24 amp. From Eq. 11 and 12, Par. 23, $I_o = \sqrt{(229.2\times 0.90)^2 + (229.2\times 0.4358 - 26.24)^2}$ = 219.0 amp.

$$\cos\theta_o = (229.2\times 0.90)/219 = 0.9420$$

$$E_g = \sqrt{[(80{,}830\times 0.9420) + (219.0\times 32.00)]^2 + [(80{,}830\times 0.3355) + (219.0\times 95.40)]^2} = 96{,}020 \text{ volts}$$

When the receiver load is removed, the substation voltage will rise. due

Digitized by Google

to the line charging current flowing through the inductance of the line. From (b) Fig. 13. $E_r$ will be, on open circuit:

$$E_r = \sqrt{E_g^2 - \left(\frac{I_c}{2}R\right)^2} + \frac{I_c}{2}X \qquad (13)$$

The $\frac{I_c}{2}R$ term is negligible. $E_r = 96{,}020 + (26.24 \times 95.40) = 96{,}020 + 2{,}500 = 98{,}520$ volts.

Regulation $= \frac{98{,}520 - 80{,}830}{80{,}830}$ or 21.90 per cent. Efficiency $= 50{,}000/[50{,}000 + (3 \times \overline{219.0}^2 \times 32.00)]$ or 91.55 per cent.

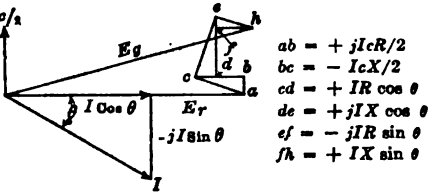

FIG. 14.—Vector diagram of line using complex quantities.

**25. The analytical solution of a nominal $\pi$ line** having appreciable capacity may be obtained by adding the voltage drops due to the load current and that due to one-half the total line charging current (passing through the line impedance) to the receiver voltage.

$$E_g = E_r + I(\cos \theta - j \sin \theta)(R + jX) + \frac{jI_c}{2}(R + jX) \qquad (14)$$

where $E_g$ = the generator voltage from phase wire to neutral; $E_r$ = the receiver voltage from wire to neutral; $I$ = the load current; $\theta$ = the phase angle of the load; $R$ = the resistance per wire; $X$ = the reactance per wire; and $I_c$ = the total charging current. The geometrical position of each quantity is shown in Fig. 14.

This diagram determines the effect upon the generator voltage of different load conditions at the receiver, the receiver voltage being kept constant.

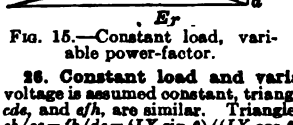

FIG. 15.—Constant load, variable power-factor.

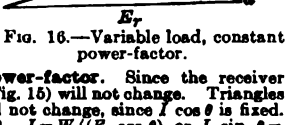

FIG. 16.—Variable load, constant power-factor.

**26. Constant load and variable power-factor.** Since the receiver voltage is assumed constant, triangle $abc$ (Fig. 15) will not change. Triangles $cde$, and $efh$, are similar. Triangle $cde$ will not change, since $I \cos \theta$ is fixed. $eh/ce = fh/de = (IX \sin \theta)/(IX \cos \theta) = \tan \theta$. $I = W/(E_r \cos \theta)$ or $I \sin \theta = W \tan \theta / E_r$. $ce$, $W$ and $E_r$ are fixed, hence $I \sin \theta$ varies as $\tan \theta$. Therefore the point $h$ must move along $eh$, toward $h'$ if the lag of the current increases and toward $e'$ if the lead of the current increases, and $eh$ must be proportional to $\tan \theta$.

**27. Variable load and constant power-factor.** (Fig. 16). $ef/cd = (IR \sin \theta)/(IR \cos \theta) = \tan \theta$.

Since $cde$ and $efh$ are similar triangles, $ef/cd = eh/ce = \tan \theta$.

Therefore, angle $ech = \theta$, which is constant, and $h$ must always lie on $ch$.

Since $cd$, and $de$, are both proportional to $I$, $e$ will move along $ce$ and $eh$ will always be perpendicular to $ce$. $\theta'$ shows the construction for a leading current.

Digitized by Google

**28. Constant voltage maintained at receiver by use of synchronous apparatus.** The generator voltage, assumed constant, will move along arc $h_2h_1$ (Fig. 17). The length $ce_1$ is equal to $I \cos \theta\ (R+jX)$ at no-load. It is then proportional to the power taken by the synchronous apparatus, and $e_1$ will move along $ce_2$ with increase of load. $e_1h_1$ is equal to $I \sin \theta\ (R+jX)$, hence is proportional to the quadrature component of the current. In order to maintain constant voltage conditions, with increase of load, $e_1h_1$ must decrease until at $e_2$ it is equal to zero and this point must correspond to unity power-factor. With further increase of load $e_1h_1$ reverses and the current leads as at $e_2h_2$. This condition may be obtained by compounding, or by changing the excitation of the synchronous apparatus, either automatically, or by hand.

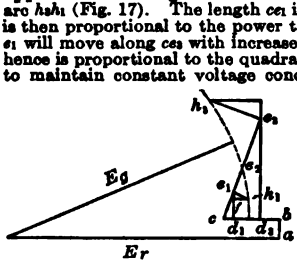

FIG. 17.—Constant voltage at receiver.

**29. Example of analytical solution of nominal $\pi$ line using complex quantity.** Consider problem of Par. 24, see Par. 25, $E_g = 80{,}830 + 229.2(0.90 - j0.4358)\ (32.00 + j95.40)$ $+ (j52.47/2)(32.00 + j95.40) = 80{,}830 + 6{,}600 + j19{,}680 - j3{,}200 - j^2 9{,}530 + j840 + j^2 2{,}500 = 94{,}460 + j17{,}320 = 96{,}020$ volts.

At no-load $96{,}020 = E_r + (j52.47/2)(32.00 + j95.40)$.

The quadrature resistance drop is negligible. Hence $E_r = 96{,}020 + (26.24 \times 95.40) = 98{,}520$ volts, which checks with the result obtained in Par. 24.

**30. Exact methods of calculating regulation** may be necessary if the line is long, the line voltage high or if harmonics need be taken into consideration. A simple method of making the necessary corrections in such cases has been developed by A. E. Kennelly.*

Fig. 18 shows a nominal $\pi$ line of linear impedance $Z = R + jX$, and a capacity admittance, $Y/2$ at each end of the line. If $R+jX$ be multiplied by $(\sinh \theta)/\theta$, and $Y/2$ by $(\tanh \theta/2)/(\theta/2)$, where $\theta = \sqrt{ZY}$, the line as far as the ends (and beyond) are concerned will behave exactly as if the line constants were uniformly distributed. The new line is then considered an *equivalent* $\pi$ and its characteristics are then calculated by the method of either Par. 24 or 25.

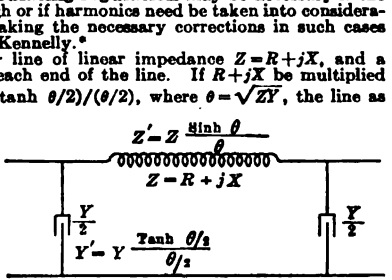

FIG. 18.—Nominal and equivalent "$\pi$" line.

**31. The general equations of the transmission line in hyperbolic functions** are:

$$E_1 = E_2 \cosh \sqrt{ZY} \pm I_2 \sqrt{Z/Y} \sinh \sqrt{ZY} \qquad (15)$$

$$I_1 = I_2 \cosh \sqrt{ZY} \pm (E_2/\sqrt{Z/Y}) \sinh \sqrt{ZY} \qquad (16)$$

where $E_1$ and $E_2$ are the respective voltages from phase wire to neutral at the sending and receiving ends of the line if the sign is assumed positive. If the sign is taken negative $E_1$ and $E_2$ are the respective voltages at the receiving and sending ends of the line. The same relation holds true for the currents, $I_1$ and $I_2$. Ordinarily the positive sign is used, as the receiver voltage and load current are generally known.

$Z$ is the impedance per wire $= R + jX$, and $Y$ is the admittance from phase wire to neutral $= G + jB$, though the leakage $G$ is usually negligible in an actual line.

Expanding the cosh and sinh terms in a converging series by Maclaurin's Theorem, and neglecting the terms after the second, the following expressions are obtained.

$$E_1 = E_2\ (1 + ZY/2) \pm ZI_2(1 + ZY/6) \qquad (17)$$

$$I_1 = I_2\ (1 + ZY/2) \pm YE_2(1 + ZY/6) \qquad (18)$$

* Bibliography 16.

**33. Example of calculation using general equation Par. 31.** Consider again the problem of Par. **24.**

$E_1 = E_s$ = generator voltage, $E_2 = E_r$ = receiver voltage = 80,830 volts. $Z = R + jX = 32.00 + j95.40$, $Y = G + jB = 0 + j6.49 \times 10^{-4}$, $I_1$ = generator current, to be determined. $I_2 = I(\cos\theta - j\sin\theta) = 229.2(0.900 - j0.4358) = 206.3 - j99.88$.

$$E_s = 80{,}830\left[1 + \frac{(32.00+j95.40)(j6.49\times10^{-4})}{2}\right] + (32.00+j95.40)(206.3-j99.88)\left[1 + \frac{(32.00+j95.40)(j6.49\times10^{-4})}{6}\right]$$

$$= 94{,}260 + j17{,}230 = 95{,}820 \text{ volts}$$

The no-load receiver voltage and the regulation may be found as in Par. **24**, Eq. 13.

Likewise $I_s$ is readily determined.

$$I_s = (206.3 - j99.88)\left[1 + \frac{(32.00+j95.40)(j6.49\times10^{-4})}{2}\right] + (j6.49\times10^{-4})(80{,}830)\left[1 + \frac{(32.00+j95.40)(6.49\times10^{-4})}{6}\right]$$

$$= 200.8 - j42.74 = 205.2 \text{ amp.}$$

**33. Charts and diagrams,** when drawn to a sufficiently large scale, are convenient for determining the electrical characteristics of transmission lines. It is essential, however, that the precision and limitations of the curves be known. Even if great refinement of calculation be desired, such diagrams are useful for checking computed results. In a handbook it is not possible to present the diagrams on a sufficiently large scale. It has seemed wise to explain their construction with data, their methods of use, and also to refer to the original articles in which they are described.

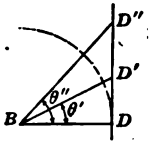

FIG. 19.

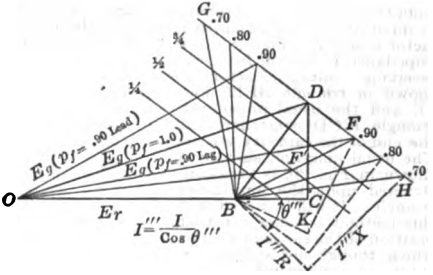

FIG. 20.

FIGS. 19 AND 20.—Perrine-Baum diagram.

**34. The Perrine-Baum* regulation diagram,** originally proposed by F. A. C. Perrine and F. G. Baum and based on the diagram shown in Fig. 13, forms a convenient method of studying transmission line regulation. To facilitate use of the diagram, the effect of phase displacement is taken into account by rotating the impedance triangle *BDC*.

The load current is proportional to $1/\cos\theta = \sec\theta$, and the impedance drop, being directly proportional to the load current, is obtained by laying off the phase angle as shown in Fig. 19. If *BD* is the impedance drop for unity power-factor, then $BD' = BD \sec\theta'$ is the impedance drop for the power-factor $\cos\theta'$, and $BD'' = BD \sec\theta''$ is the drop for the power-factor $\cos\theta''$, etc.; that is, the impedance-drop vector always terminates on a straight line, drawn at right angles to the drop *BD* for unity power-factor.

The diagram is shown in Fig. 20, in which the line capacity is neglected. Its use will be clear from the following example:

* Bibliography 1.

Digitized by Google

**35. Example of calculation using Perrine-Baum regulation diagram.** Assume 1,000 kw. to be transmitted to a substation at 90 per cent. power-factor, lagging, the voltage at the substation to be maintained constant at 10,000 volts. The line has a resistance of 8 ohms and an inductive reactance of 15 ohms. The line capacity is neglected. With unity power-factor the line current is 1,000,000/10,000 = 100 amp. Referring to Fig. 20, lay off $OB = 10{,}000$ volts, $BC = 100 \times 8 = 800$ volts, and $CD = 100 \times 15 = 1{,}500$ volts. If the power-factor were unity, $OD$ would be the voltage at the generating station. To determine the generator voltage for 90 per cent. power-factor, lagging, draw $GH$ perpendicular to $BD$ and lay off to the right of $BD$ an angle, $DBF$, whose cosine is equal to 0.90. The line impedance drop will be represented by $BF$, hence $OF$ shows the voltage at the generating station for this power-factor. For any other power-factor, cos $\theta$, lay off the angle $\theta$ to the right of $BD$ for lagging currents, and to the left of $BD$ for leading currents. The voltage at the generating station will be determined by the line joining $O$ with the terminal of the line impedance drop for the given cos $\theta$. For other loads, hence other values of line current, $BD$ is divided into proportional parts, and lines parallel to $GH$ are drawn as shown. For example, the voltage at the generating station at one half-load and with a power-factor of 0.9 (lagging), is represented in the diagram by the line $OF'$.

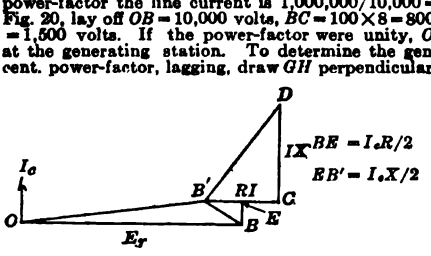

FIG. 21.—Effect of charging current.

Line capacity is taken into account by assuming a constant load voltage; from this assumption the charging current is calculated, taking this current as in quadrature, leading, with respect to the receiving voltage, if the power-factor is unity. The drop due to the charging current in one-half the line impedance is laid off from the receiving voltage vector as shown in triangle BEB', Fig. 21, and the usual impedance triangle B'CD constructed at the end of the capacity vector. The usual diagram, such as is shown in Fig. 20, is then constructed upon the impedance triangle. It will be noted that this method assumes constant position of the capacity vector, which, though not strictly accurate, is sufficiently so for most purposes in overhead line calculation, except for lines of great length. Compared to the errors due to non-sinusoidal voltage wave the error due to this capacity effect is negligible.

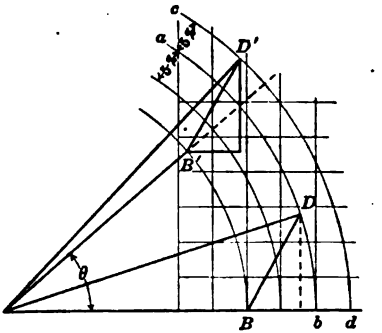

FIG. 22.—Mershon diagram.

**36. The Mershon* diagram.** If the e.m.f. diagram shown in Fig. 3 is rotated about $O$ as a centre through an angle $\theta$, where cos $\theta$ is the power-factor, and all e.m.fs. are expressed in per cent. of the voltage generated at unity power-factor, the line drop, neglecting capacity effect, being measured along a radius with centre $O$, then a simple diagram for determining regulation may be developed. Such a diagram is constructed by drawing a series of concentric circles $ab$, $cd$, etc. (Fig. 22) upon a coordinate system of equal squares; a side of one of these squares is equal to the difference in radii between any two consecutive circles. The radius $Ob$ is taken as 100 per cent., and the coordinate spaces may conveniently represent intervals of 5 per cent.

* Bibliography 22.

Digitized by Google

The power-factor is cos $\theta$ and is numerically equal to the projection of $OB'$ upon the horizontal axis. Having definite line constants, and with a load of given power-factor, the resistance and the reactance voltage drops are calculatedin per cent. of the receiver voltage. Starting at the foot of the ordinate representing the load power-factor, follow this ordinate up to its intersection with the first circle, which is the locus of the point $B$ of the impedance triangle. From this last point lay off on the coordinates the impedance triangle. The circle upon which the apex $D$ lies will give the per cent.drop directly. The diagram constructed to scale is given in Sec. 12, Fig. 11, and the table of Sec. 12, Par. **31** is calculated for use with it.

**37. Example showing use of the Mershon diagram.** A transmission of 250 kw. at 80 per cent. power-factor, lagging, is to be made at 2,000 volts to a receiver 10,000 ft. distant from the generator. The frequency of the system is 60 cycles per sec.; the size of wire No. 0; the spacing of the line wires 18 in. Find the line loss and the line drop. $250{,}000/0.8 = 312{,}500$ apparent watts. $312{,}500/2{,}000 = 156.25$ amp.

From Par. **31**, Sec. 12 for 18 in. spacing and No. 0 wire the reactance constant is 0.228.

$0.228 \times 10 \times 156.25 = 356.3$ volts. $356.3/2{,}000 = 0.178$ or 17.8 per cent.

From Sec. 12, Par. **31**, the resistance constant for No. 0 wire is 0.196. $0.196 \times 10 \times 156.25 = 306.3$ volts. $306.3/2{,}000 = 0.153$ or 15.3 per cent.

Now referring to the diagram, Fig. 11, Sec. 12, starting at 0.8 power-factor, follow the vertical ordinate to its intersection with the curve, 0. From this point lay off the resistance drop, 15.3 per cent., parallel to the base of the diagram, remembering that a side of each square represents 5 per cent. Then from the extremity of the resistance drop lay off the reactance drop, 17.8 per cent., parallel to the altitude, again using the squares. The end of this line will be found on circular arc 23. This then is the total drop given in per cent. of the receiver voltage. The generator voltage is:

$$23/(100+23) = 0.187 \text{ or } 18.7 \text{ per cent.}$$

greater than the receiver voltage. The total line-drop then is 18.7 per cent. The $I^2R$ loss is

$$306.3 \times 156.25 = 47.9 \text{ kw.},$$

and, in per cent., is

$$47.9/(250+47.9) = 0.161 \text{ or } 16.1 \text{ per cent.}$$

In order to find the size of wire necessary for a given drop one must solve by trial and error. Assume a size of wire and solve for the drop. This first error will indicate the proper choice for a second trial, etc., as in Par. **14**.

## GENERAL FEATURES OF DESIGN

**44. The conductor** for a given transmission system is influenced by such factors as climate, topography, length of span, reliability, amount of power, transmission distance and the economics of the problem. Copper and aluminum (see Sec. 4), except in special cases, are used exclusively for the conductors. Copper has high conductivity, is very ductile, is not easily abraded, has high tensile strength, a high melting point, and can be readily soldered. Aluminum has a conductivity about 60 per cent. that of copper. For the same conductance, it has only one-half the weight of copper. It is ductile and easily abraded; has 1.4 times the linear coefficient of expansion of copper, giving greater sag, and would therefore require higher towers for the same length of span. The tensile strength is much less than that of copper, though the ratio of tensile strength to weight is greater for aluminum. The melting point of aluminum is lower than that of copper, so that aluminum will be more easily burned by arcs and short-circuits. For the same conductance, aluminum offers a greater surface to wind-pressure, so towers must be designed with greater transverse strength. Neither copper nor aluminum is attacked by the atmosphere to any extent. In the United States, the price of aluminum is always held slightly below that of copper of the same conductance. In view of increased cost of pole line necessary to its employment, there is comparatively little incentive to use aluminum in small sizes of wire. In Canada and on the Continent of Europe, aluminum has found favor.

**45. For extra long spans,** it may be found economical to use either iron or steel as conductors, because of their much greater tensile strength. As these metals are subject to corrosion, they must either be galvanized or "copper-clad." Phosphor-bronze has been proposed, but its much higher cost for the same conductance practically prohibits its use. The table in Par. 46 shows a comparison of various conductor materials, and more complete tables may be found in Sec. 4.

**46. Comparison of conductor materials on basis of equal conductance**

| Metal | Diameter | Weight | Strength | *Cost relation |
|---|---|---|---|---|
| Copper | 1.00 | 1.00 | 1.00 | 1.00 |
| Aluminum | 1.27 | 0.485 | 0.65 | 2.06 |
| Iron | 2.72 | 6.36 | 5.30 | 0.157 |
| Steel | 3.41 | 10.00 | 41.5 | 0.100 |
| Copper-clad steel | 1.52 | 2.12 | 4.46 | 0.47 |

NOTE.—Skin effect has been neglected. Skin effect tables are given in Sec. 4. The relative resistances have been taken as follows: copper = 1; aluminum = 1.61; iron = 7.4; steel = 11.6; copper-clad steel = 2.3. The specific gravities are: copper = 8.89; aluminum = 2.68; iron and steel = 7.64; and copper-clad steel = 8.20. The elastic limits are: copper = 35,000 lb. per sq. in.; aluminum (stranded) = 14,000 lb. per sq. in.; iron = 25,000 lb. per sq. in.; steel = 125,000 lb. per sq. in.; and copper-clad steel = 68,000 lb. per sq. in.

**47. Required size of conductor is determined** by (a) mechanical strength; (b) permissible energy loss; (c) required voltage regulation; (d) corona; (e) cost; (f) current-carrying capacity.

(a) **Mechanical strength** is a primary consideration in any transmission line. It becomes especially important where long spans are necessary.

(b) **Permissible energy loss** is determined by such factors as the cost of generating power, selling price, load-factor, and other economic considerations. Where power is produced cheaply, it may be more economical to lose power in the line than to pay the fixed charges incident to heavier conductors and poles. (See Economics.)

(c) **Required voltage regulation** is, in general, not difficult to secure, as automatic regulators and synchronous apparatus may take care of any

* The last column in the table shows what *should* be the relation in cost per lb. of the various materials to result in the same total cost of conductor where the conductance of the line is fixed.

Digitized by Google

voltage fluctuations at the substations. If, however, the inductive line drop for a given cross-section of conductor is too great, two separate lines of half the cross-section may be used. The additional cost of insulators, poles and construction seldom justifies duplicate lines, where better regulation alone is the requirement.

(d) **Corona** may make the energy loss in excess of the permissible value, in which case, it will be necessary to increase the conductor diameter or the effective size of conductor. See Par. **48** to **53**.

(e) **Cost**, such as the relative cost of line, of plant, and of line maintenance may determine the size of line conductors. Since the salvage value of the line is in general low, whereas the engines and dynamos of the central station may be transferred without excessive loss to another plant and again used, it is advantageous to put more money into the generating station and to build the line as cheaply as possible if the system is a temporary affair. The amount of money available may make it necessary to build the system at a minimum cost, in which case the line conductors must be so chosen that the cost of the line plus the cost of the station, to supply both the net load and the line loss, shall be a minimum. The larger the line conductors, the smaller will be the energy loss, but the fixed charges for the line will be increased. The conductors may be so chosen that the sum of these last two quantities is a minimum. See Par. **225**.

(f) **Current-carrying capacity** of the conductors under continuous operating conditions, is usually ample when the size of wire is determined by the permissible energy loss. An emergency demand, however, may overload the line for a short time, and where this is likely to occur, the conductor should be of such size as to operate within safe temperature limits. Tables of safe carrying capacity are given in Sec. 12.

## CORONA

**48. Corona**, or the luminous discharge into the atmosphere from conductors at high voltage, may result in a considerable loss of power. H. J. Ryan, R. D. Mershon, J. B. Whitehead, and F. W. Peek have made studies of this phenomenon. *Peek's results are the latest obtained under actual operating conditions, and their accuracy is unquestioned. The relations may be expressed by the following formulæ:

The visual critical voltage is:

$$E_v = M_v\, g_o \delta r \left(1 + \frac{0.301}{\sqrt{\delta r}}\right) \log_e \frac{S}{r} \text{ kv. to neutral} \qquad (19)$$

$$P = \frac{k}{\delta} f \sqrt{\frac{r}{S}} (e - e_o)^2 10^{-5} \text{ (per kilometer of single conductor)} \qquad (20)$$

where $e_o = g_o M_o r \delta \log_e \frac{S}{r}$

$e_o$ is the *disruptive critical voltage* to *neutral* and is always lower than $E_v$. The tables in Par. **49** and **50** give values of $e_o$.

(To obtain kw. per mile, multiply by 1.61)

Where $E_v$ = effective kilovolts from phase wire to neutral at which corona becomes visible. $M_v = M_o = 1$ to 0.93 for wires, the higher value applying to a polished wire. $M_v = 0.72$, local corona all along conductor and 0.82, decided corona all along conductor for seven-strand cables; $g_o = 21.1$ kv. per cm., being the dielectric strength of air at 25 deg. cent. and 76 cm. pressure; $\delta$ = air density factor $= 3.92b/(273+t)$; $\delta = 1$ at 76 cm. pressure and 25 deg. cent. $b$ = barometric pressure, in cm.; $t$ = temperature deg. cent.; $r$ = radius of conductor, cm.; $S$ = distance between centres of conductors, cm.; $\log_e = 2.303 \log_{10}$; $P$ = power per kilometer wire, kilowatts; $k = 344$; $f$ = frequency cycles per sec.; $e$ = effective kilovolts to neutral of conductor; $M_o$ = irregularity factor of conductor; $M_o = 1$ for polished wires; 0.98 to 0.93 for roughened or weathered wires; 0.87 to 0.83 for seven-strand cable.

*For three wires equally spaced in a plane*, an exact calculation is too complicated for practical work. If the average spacings are assumed in calculating the critical voltage, corona will start on the centre conductor at a voltage about 5 per cent. lower than the calculated value, and on the two outside conductors at a voltage about 5 per cent. higher than the calculated value. For practical work it is sufficiently accurate to neglect this correction unless the spacing is quite uneven.

Total Line Loss
Fair Weather Line Loss = 0.0104 (e − 65.5)²
Kilowatts Loss
Kilovolts between Lines

FIG. 23.—Corona loss during snowstorm.

In calculating corona loss, it must be remembered that the entire line is not at the same potential, and that a small change in e.m.f. above the critical value, $e_o$, makes a large percentage change in the loss. It has been suggested to make use of this last fact in dissipating energy associated with an abnormal rise of voltage due either to a line surge or to lightning.

The part of the loss curve between $E_v$ and $e_o$ is affected to a considerable degree by the conditions of the wire surface as to dirt, weather, etc., and hence varies from day to day. In practice it is generally not advisable to operate at a higher voltage than that corresponding to $e_o$, otherwise the loss would become very high during wet weather or when the conductor surface became roughened. Local brushes also occur which may cause deterioration of the conductor by nitric acid formation, especially at the points of support. The voltages in the tables (Par. **49**) correspond to $e_o$ voltages reduced to kilovolts between conductors at 25 deg. cent. and 76 cm. barometer.

**49. Corona limits of voltage. Kilovolts between lines (three-phase) at sea level**

To find the voltage at any altitude, multiply the voltage found above by the $\delta$ corresponding to the altitude as given in Par. **50**.

For single-phase or two-phase circuits find the value of volts for the corresponding three-phase circuit above, and multiply by 1.16.

**50. Altitude correction factor $\delta$**

**51. To decrease corona loss,** either the frequency or the voltage must be reduced. These, however, are usually fixed. The spacing may be increased, but this decreases the loss but slightly, and the increased conductor spacing would increase the line cost considerably. As the meteorological conditions cannot be controlled, the diameter of conductor must be increased. This may be done without increasing the conductor weight by using aluminum, hemp- or steel-cored cable, or hollow conductors. The first is the most practicable method and in future, it may become necessary to use aluminum for very high voltage lines. Hemp-cored cable has been tried, but the core soon rots and the conductor strands become disarranged. Hollow conductors reduce the skin-effect, but the cost of manufacture makes their use prohibitive.

**52. Example of calculation of corona loss.** Line, 3-phase; length of line, 120 miles; size conductor, 00 copper; e.m.f., 110 kv.; frequency, 60 cycles; spacing, 10 ft. Assume 20 deg. cent., 76 cm. barometric pressure, and a coefficient of roughness, $M_c = 0.95$. $d = (3.92 \times 76)/(2.73 + 20) = 1.01$; diameter of 00 wire = 365 mils; $r = 0.463$ cm.; $S = 10 \times 12 \times 2.54 = 305$ cm.; $e = 110/\sqrt{3} = 63.5$ kv., to neutral; $e_0 = 21.1$ kv.; $\log_{10} \frac{305}{0.463} = 2.82$; $P = \frac{344}{1.01} \times 60 \times 0.039\ [63.5 - (21.1 \times 0.95 \times 0.463 \times 1.01 \times 2.303 \times 2.82)]^2 \times 1.61 \times 10^{-5} = 797(63.5 - 60.9)^2 \times 1.61 \times 10^{-5} = 0.0864$ kw. per wire per mile; total corona loss $= 0.0864 \times 3 \times 120 = 31.1$ kw.

## LINE INSULATORS

**53. Requirements.** The successful operation of a transmission system depends to a large extent upon the degree of insulation attained, and the most important factor is the insulator. Up to a few thousand volts, there is no difficulty whatever in maintaining good insulation, but as the voltage reaches higher values, the difficulties increase and factors such as leakage and capacity effects, which are entirely negligible in low-tension systems, become of major importance.

Digitized by Google

**54. Insulators have appreciable capacity,** and act like condensers of complicated construction. The dielectric is made up of alternate layers of air and porcelain or glass of varying thicknesses. Some of the charging current to the pin must pass over the surface of the insulator, which has a very high resistance, so the insulator may be represented by a resistance, shunted by a number of small condensers as shown in Fig. 24, where $E$ is the voltage from the line to the pin, $I$ the total current taken by the insulator, $i_c$ the charging current, and $i_r$ the leakage current. The vector diagram simply illustrates the theory, and no attempt has been made to give the proper relative values to the various quantities. *Measurements by C. E. Skinner

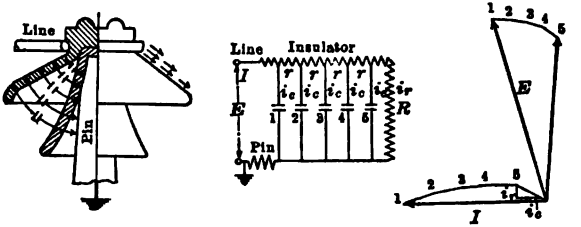

FIG. 24.—Insulator, equivalent circuits.

indicate that the ohmic resistance of porcelain insulators is practically infinite, and that whatever leakage takes place passes over the surface. The effect of capacity tends to increase this surface leakage, which ionizes the air, and thereby decreases the leakage resistance. Insulators should, therefore, be designed with small petticoat areas; the material should have a low dielectric flux constant, and the capacity should be so distributed that there will be no local stresses tending to cause a breakdown. Flaring the petticoats increases the thickness of the dielectric and decreases its dielectric flux constant, since that of air is only about one-fifth that of porcelain; therefore, by flaring the petticoats the electrostatic capacity of the insulator is greatly decreased.

**55. Insulator adapted to wet-weather conditions.** A German firm has substituted a metal top for the topmost petticoat and found that the ability to stand up under high tension is increased, other things being equal. The substitution of metal for porcelain does away with the surface resistance to the charging current on the top petticoat, and equalizes the static strains when the insulator is wet. The tendency is to drive the water to the edge and repel it. This fact is borne out by test. When perfectly dry this type will break down at a slightly lower voltage than a similar one with a porcelain top; due to the extreme lightness of the top, it may be made very broad and its action in rain is to shield the porcelain part of the insulator. In this way the breakdown voltage is considerably increased over that of the ordinary all-porcelain insulator of the same weight.

**56. The minimum arcing distance and leakage path** are shown in Fig. 25, as $A+B+C$, and $ab$ respectively. The resistance is directly proportional to the length and inversely proportional to the area of the path, so increasing the diameter of the petticoats does not increase the leakage resistance appreciably. Increasing the number of petticoats increases the length of path without necessarily increasing the area, so that a high leakage resistance is best secured by increasing the number of petticoats. Insulators are usually made of glass, porcelain, or patented compounds.

**57. Glass** is cheaper than porcelain and when properly annealed, has high dielectric strength and specific resistance. As it is transparent, flaws can readily be detected. On the other hand, moisture condenses on its surface; the action of rain destroys the smoothness of the surface and allows particles of dirt to accumulate diminishing the resistance of the leakage path.

*Measurements made for Ralph D. Mershon, *Trans.* A. I. E. E., Vol. XXVII (1908), p. 928.

Digitized by Google

**58. Porcelain** gives less leakage trouble, is stronger mechanically than glass, and is less affected by changes of temperature. On the other hand, it is more expensive, and slight imperfections in the glaze are common. As flaws, such as blow-holes, strata, or cracks cannot be readily detected by simple inspection, each section should be subjected to a voltage test before and after assembling.

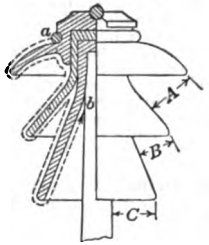

FIG. 25.—Arcing and leakage paths.

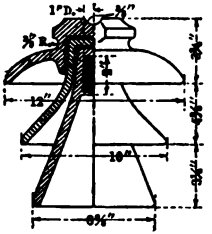

FIG. 26.—Pin-type insulator.

**59. Patented compounds** are on the market, possessing better mechanical characteristics than either porcelain or glass. It is somewhat doubtful, however, if these compounds can successfully withstand the effects of weather and the high electrostatic stresses incident to high-tension power transmission.

**60. Pin-type insulators** are made of either glass or porcelain. Glass insulators of this type are now being manufactured to operate at 50,000 volts pressure. Porcelain pin-type insulators can be used for pressures as high as 90,000 volts. (See Fig. 26.)

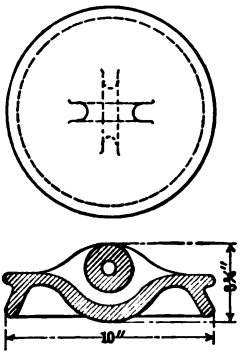

FIG. 27.—Hewlett suspension insulator.

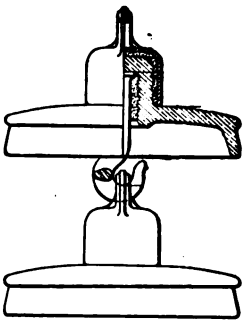

FIG. 28.—One-piece cemented insulator, suspension type.

**61. Suspension insulators** can be operated at about 20,000 volts per unit, and are used for voltages in excess of 70,000, as the pin-type insulator then becomes too large, heavy, expensive, and mechanically weak. When suspension insulators are used, the cost and weight are practically proportional to the line voltage, but beyond a certain point it is difficult, even with additional units, to secure increased insulation. There are two common types, the Hewlett, or interlinking type of insulator, shown in Fig. 27, where the two suspension cables loop through each other and are separated by a layer

Digitized by Google

of porcelain; and the cemented type, in which the porcelain or glass is cemented into a metal cap, and the pin is cemented into the insulator. Fig. 28 shows a one-piece cemented unit and Fig. 29 shows a two-piece cemented unit. The Hewlett type has not as yet met the mechanical requirements of very heavy power work. It is probably more difficult to replace than the cemented type, and the electric stresses are not so well distributed. The cemented type has given trouble due to failures at the base of the cap, and in design this factor should be carefully considered. The present tendency in insulator design is toward smaller discs and closer spacing. This results in higher puncture strength for a given flash-over voltage.

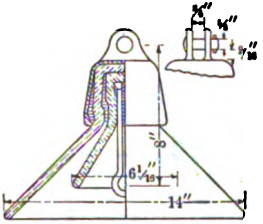

FIG. 29.—Two-piece cemented insulator, suspension type.

**62. The string efficiency*** of $n$ suspension insulator units is the ratio of their total flash-over voltage, to $n$ times the flash-over voltage of one insulator. Although certain unpublished 500,000-volt tests have shown this ratio to be practically unity, the majority of experiments show that the string efficiency decreases when the number of insulators is increased. Fig. 30 shows the results of the tests made by F. W. Peek, Jr. This lowering of flash-over voltage is due to the fact that each insulator has a certain capacity to ground, the insulator nearest the line carrying the charging current of the whole string of $n$ insulators. The second insulator carries the charging current of $n-1$ insulators, etc., so the unit next the line is subjected to the greatest stress, the second unit to a lesser stress, etc. The string efficiency is nearer unity under the wet test, as the leakage current is then so increased that the effect of the capacity current is negligible. The string efficiency is increased by making the ratio of mutual capacity to ground capacity large; that is by hanging the insulator units near together but having each string at some distance from the pole or tower. (Par. 67.)

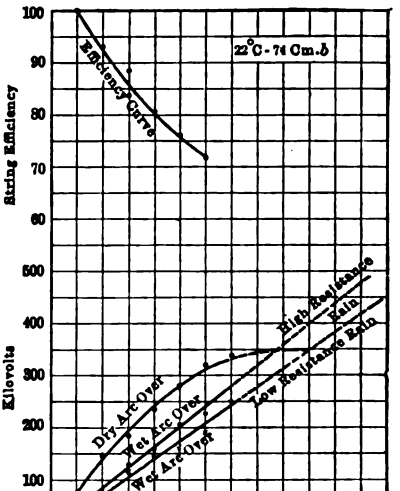

FIG. 30.—Insulator string efficiency.

**63. The Watts insulator**, shown in Fig. 31, proposed by *A. S. Watts, of Germany, is 1 ft. long and has withstood 100,000 volts. It is claimed that in so far as cost and weight go, this insulator is similar to the suspension type, in that the cost and weight are about proportional to the voltage. The small grooves are not so deep that they will collect dirt and foreign material which can-

* Bibliography 39.

Digitized by Google

not be removed by the action of the elements. If struck by lightning the charge can pass to ground by jumping from one ridge to another, and the insulator will remain unharmed.

**64. Strain insulators** are used when the line is dead-ended; at intermediate anchor towers; on sharp curves where the line would tend to overturn the insulator, break the pin, or pull a string of suspension insulators out of alignment; and on extra long spans, as at river crossings. For voltages up to

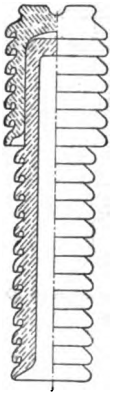

FIG. 31.—The Watts insulator.

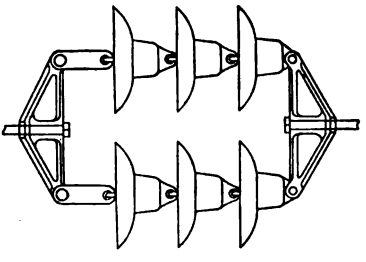

FIG. 32.—Strain insulator with yoke.

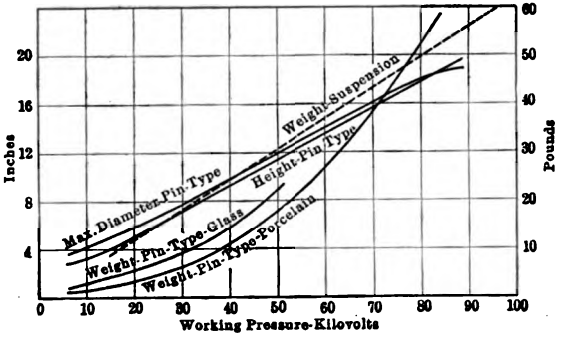

FIG. 33.—Weights and sizes of insulators.

30,000, a pin-type may be used. For voltages in excess of 30,000, either the link-type or the cemented type (Fig. 32) is used. Fig. 33 gives the approximate sizes and weights of the various types of insulators.

**65. Insulators are usually designed to flash over, rather than to puncture.** To assist in securing this result, particularly on high frequency impulses, arcing rods are used (Fig. 35). These have the further effect of

* Bibliography 35.

Digitized by Google

holding the power arc away from the insulator. Another type is the *Nicholson arcing ring. (Fig. 34.)

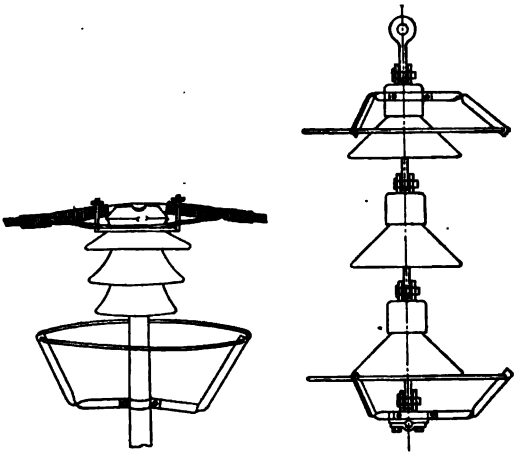

FIG. 34.—Nicholson arcing rings.

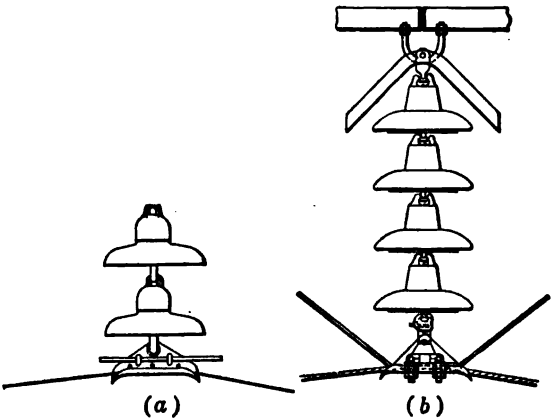

FIG. 35.—Arcing rods.

**66. The line conductor should also be protected from burning off,** due to the heat of the arc. The arcing rods shown in Fig. 35, and the Thomas Line Protector shown in Fig. 36 may be used.

* Bibliography 36.

Digitized by Google

**67. *Effect of high frequency on insulators.** Insulators that only flash over at commercial frequencies may puncture at the same voltage if the frequency be high. This is probably due in part to the altering of stress distribution caused by the change in the ratio of susceptance to leakage conductance brought about by high frequency. It is also due in part to the corona not having time to form and relieve the stress by rupture of the air. To prevent puncture due to high frequency disturbances, the ratio of flash-over voltage to puncture voltage should be low.

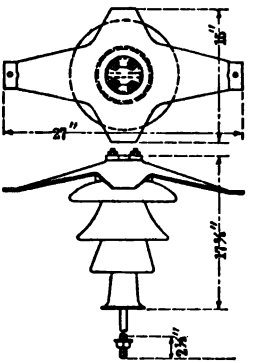

FIG. 36.—Thomas line protector.

**68. Insulator testing†** is of two kinds, design tests and routine tests. Design tests cover those features that are important to the purchaser, such as dry and wet flash-over, puncture voltage, tensile strength, and are usually made on the assembled unit or string. The insulator should be tested under conditions approximating those attained in service, such as mounting or suspending from a grounded pin and cross arm, well away from other objects. The potential should be applied between the pin, and a short length of cable, representing the line conductor, tied or clamped to the insulator. The standard wet test is to spray water over the insulator at an angle of 45 deg. and at a precipitation rate of 0.2 in (0.508 cm.) of water per min. As results are largely dependent on the electrolytic nature of the water, distilled water is to be preferred, as more uniform results are obtained by its use. Insulators, under ordinary conditions, flash over before puncturing, so in order to obtain the puncture voltage, the insulators must be immersed in oil.

Routine tests should be made on each part of every insulator before assembling, and also on the complete unit. The object is not to flash over the insulator but rather to detect existing faults before the insulator is put in service. The parts of pin and suspension type insulators are inverted in water thus forming one terminal. Water is also placed inside the insulator

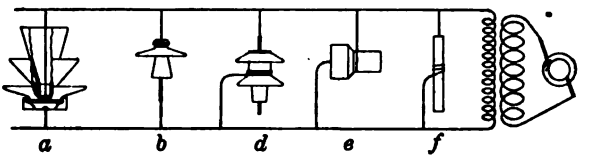

FIG. 37.—Insulator testing.

covering the threads in the threaded parts, and from 0.5 to 0.75 in. (1.27 to 1.9 cm.) deep in the other parts, thus forming the other terminal as shown in a, Fig. 37. Dry tests are often made on the assembled unit, b, c, d, e (Fig. 37) and are necessary on strain insulators and bushings. The *breakdown voltage of insulators* is a function of the time during which the voltage is applied, as has been shown by A. O. Austin.‡ A higher potential for a short time will eliminate poor insulators in the same manner as a lower potential for a longer time. Such curves for 100 kv. and 85 kv. are shown in Fig.

* See Bibliography 40.
† See Bibliography 34, 37–41 incl.
‡ See Bibliography 37.

Digitized by Google

38. Thus 100 kv. for one-half minute will eliminate 2.2 per cent., whereas 85 kv. must be applied 4.7 minutes to produce the same result.

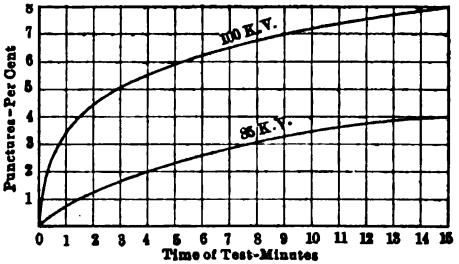

FIG. 38.—Insulator time-puncture curves.

## SYSTEM DISTURBANCES

**69. Surges* and disturbances** occur in a transmission circuit, when circuit conditions are in any way altered. An **oscillation** is a recurring disturbance due usually to the oscillation of energy between the electrostatic and electromagnetic fields. An oscillation of low frequency, or one that is rapidly damped, is called a **surge.** Disturbances may be produced by causes within the system itself, such as switching, grounds, changes of load, or they may be produced by external causes, such as lightning.

In an oscillation, the energy passes from one form to the other, so that assuming no loss,

$$\tfrac{1}{2}Li^2 = \tfrac{1}{2}Ce^2$$

or

$$e/i = \sqrt{L/C} \qquad (21)$$

The term $\sqrt{L/C}$ is the *natural impedance* of the line.

From Eq. 21, the maximum voltage possible to occur on interruption of the current $I$ is:

$$e = I\sqrt{L/C} \qquad (22)$$

This rise of voltage limits the current that may safely be interrupted and renders a short circuit dangerous.

Any change in load will alter either $e$ or $i$ and as the energy of the electrostatic and electromagnetic fields cannot change in zero time, $e$ and $i$ must pass through some transient values before the steady state is again reached.

If $r$, the resistance, is equal to or greater than $\sqrt{L/C}$, the transient is non-oscillatory, and quickly dies out. If $r$ is less than $\sqrt{L/C}$, the transient is oscillatory. The energy is dissipated as heat in the resistance, in hysteresis losses in the fields themselves, or the insulation of the system may break down allowing the energy to manifest itself in an arc.

**70. The frequency at which the transient oscillates** is

$$f = 1/(4\sqrt{LC}) \qquad (23)$$

when the circuit constants are distributed, as in the case of a transmission line. $f$ is the *natural frequency* of the circuit. The transmission frequency should be so chosen that the natural frequency is not exactly an odd multiple thereof.

**71. Forced oscillations** are produced by a source of energy external to the circuit, such as lightning, whose frequency has no relation to the circuit constants.

* Par. 247.

Digitized by Google

**72. Effect of transients.** When a traveling wave passes from one part of a circuit into another of different constants, the voltage wave, $e_1$, will change its magnitude to $e_2$, as follows,

$$e_2 = e_1 \frac{Z_2}{\left(\frac{Z_1+Z_2}{2}\right)} \tag{24}$$

and the current

$$i_2 = i_1 \frac{Z_1}{\left(\frac{Z_1+Z_2}{2}\right)} \tag{25}$$

where $Z_1$ and $Z_2$ are the natural impedances $\sqrt{L_1/C_1}$ and $\sqrt{L_2/C_2}$ of the two parts of the circuit, respectively. (See Par. 69.) Thus a wave passing from one part of a circuit to another having a greater ratio of inductance to capacity will develop an increased voltage and a decreased current. This explains the breaking down of transformer windings, due to surges entering them. On the other hand, if a wave passes from an overhead system into a cable, the voltage will be reduced, and the current increased. This explains the self-protecting quality of cables to surges.

**73. A line whose length is a quarter wave** is determined by

$$L = \frac{183{,}000}{4f} \tag{26}$$

where $L$ is the length in miles, $f$ the frequency in cycles per sec., and 183,000 the velocity of an electric wave in miles per sec. It can be shown that such a line, with constant generator voltage, tends to regulate for constant current at the receiving end, and the maintenance of constant voltage at the load therefore becomes difficult. The voltage may rise to dangerous values when the circuit is opened, though a transformer at the receiving end will practically neutralize this abnormal potential. The frequency corresponding to a quarter wave length of line is the lowest frequency at which the line can freely oscillate. It cannot oscillate at a frequency corresponding to either a half or a whole wave length when the circuit is open at one end.

**74. Oscillations originating in the transformer.** High voltage transformers have an appreciable electrostatic capacity between turns, and also to ground, together with a large equivalent reactance. This not only tends to create very high frequency oscillations in the transformer itself but also to produce voltage rises that may puncture the insulation. Protective apparatus must therefore be so designed that these oscillations may readily pass from the transformer to the line, and, at the same time, outside disturbances will be prevented from passing in the reverse direction.

**75. Lightning disturbances*** may be due to a charge induced on the line by a nearby cloud which discharges, thus allowing the line charge to flow suddenly to ground; to inductive action of a nearby discharge; to direct stroke. Such disturbances may be of high frequency and may either start a destructive arc to ground or shatter the insulators near the spot of original disturbance. Waves may be propagated in both directions, causing damage at some remote point.

**76. Lightning disturbances may be minimized** by the use of one or more overhead ground wires, grounded at very frequent intervals. Damage to apparatus may be practically prevented by installing arresters, preferably of the aluminum cell type, near the apparatus, for example, across the high-tension bus bars at the generating station, at substation entries, and near outdoor transformers and substations. Lines have been protected by operating them just below the critical corona voltage (see Par. 48 to 52). Any disturbance that tends to raise the voltage, immediately increases the corona loss to such an extent that the energy of the disturbance is thereby dissipated.

**77. The selection of protective equipment** is governed somewhat by local conditions. The degree of protection necessary depends largely upon the value of the power that is being transmitted, and the financial loss involved by a shut-down or by an interruption of the service.

* Bibliography 56.

Digitized by Google

**78. Local short-circuits** may be isolated from the rest of the system by properly selected automatic oil switches equipped with relays which are of either the instantaneous, reverse-energy, or inverse-time-limit types. Lightning arresters should be able to care for any abnormal voltage rise due to switching. (See Par. **69** and **92**.) That the current flowing into a short circuit in one portion of the system may not rise to dangerous values, power-limiting reactances are interposed between the different sections of the system

**79. Detection and clearing of grounds.** Grounds may be detected by some form of electrostatic detector, placed on the switchboard. An arcing-ground on an ungrounded system may be cleared by the **arcing ground suppressor,*** shown in Fig. 39. The selective relay may operate electrostatically, or electromagnetically by the use of potential transformers. When a ground occurs on any phase, that phase is temporarily grounded by the proper oil switch, selectively operated by the relay. This lowers the voltage across the arc, which therefore ceases, and the switch then opens (through a resistance to prevent oscillations) and the ground is thus cleared. In a cable system the grounded phase is permanently connected to ground, as otherwise the arc would immediately re-form when the switch opened, due to the short distance between core and sheath. Interlocking devices prevent the simultaneous operation of more than one switch at a time, thus avoiding a short circuit on the system.

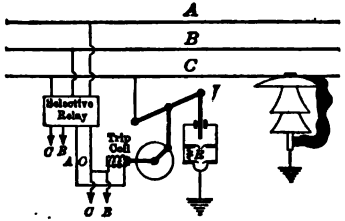

FIG. 39.—Arcing-ground suppressor.

A **short-circuit suppressor** throws a fuse directly between phases, shunting out a short-circuit arc. Subsequently the fuse automatically interrupts its own current. When these are used, power-limiting reactances are desirable in order to protect apparatus from mechanical injury.

**80. Overhead ground wires** unquestionably reduce the interruptions to service due to lightning, although there are no available data stating just how great the advantage is. It is estimated that one wire will reduce these interruptions about 50 per cent., and that two wires will make a still greater reduction. Galvanized iron and steel, because of their low cost and high tensile strength, have been commonly used for this purpose. Copper-clad conductors may have a lower impedance to the high-frequency discharges of lightning than have galvanized iron or steel.

## SYSTEM CONNECTIONS AND SWITCHING

**81. System connections should be made** in such a manner that continuity of service, flexibility, and safety are secured without undue complications of wiring and switching.

**82. Duplicate lines** are usually necessary, where continuity of service is important. It is customary to run the two lines on the same poles or towers, especially if these are of steel or concrete, as the total cost of line supports is then much less than it would be for two individual pole lines. Where the power is especially valuable, the two lines may be run over two different routes, removed from each other. This lessens the chance of both lines being disabled at the same time by lightning or by other natural causes. The cost of two such lines is frequently prohibitive. When it is necessary to shut down a line for repairs, the service is interrupted if two lines are not available. Where the regulation would be impaired, or the overload capacity of one line is not sufficient to carry the entire load during such a shut-down, sectionalising switches may be provided. The section requiring repairs may be isolated and grounded, the two lines being in parallel for the remaining distance. This insures better and more continuous service, though frequently the advantage gained is more than offset by the added expense and

* See Bibliography 56.

Digitized by Google

switching complication. Fig. 40 shows the connections for a typical power system.

**83. Substation connections** are made as shown in Fig. 40 and Figs. 73 and 74. See also Sec. 10 and Sec. 12.

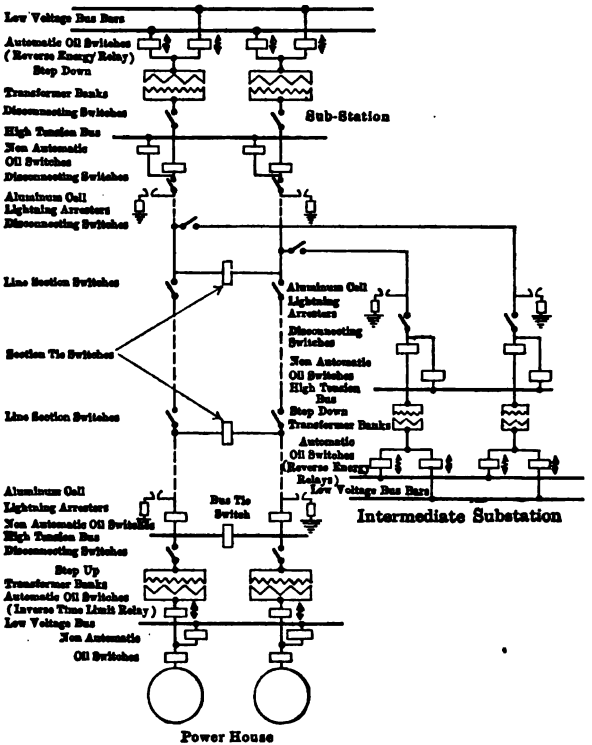

FIG. 40.—Typical system connections.

**84. *Advantages of grounded systems are as follows:** (a) Except under unusual transient conditions, the voltage from line wire to ground never exceeds the $Y$ voltage, so the line insulation need not have so large a factor of safety, as with isolated systems; (b) a ground on one wire opens the breakers and warns the operator of trouble; (c) the dynamic arc to ground has but little tendency to create high frequency oscillations; (d) disturbances to the telephone system due to electrostatic unbalancing are a minimum.

**85. Disadvantages of grounded systems are:** (a) The line is inoperative if a ground occurs; (b) the short-circuit current may produce strong mechanical forces in generator and transformer windings, causing

* See Bibliography 67, 68.

Digitized by Google

serious damage; (c) the dynamic arc may shatter the insulators or burn off the conductors, because of the large amount of energy available; (d) inductive effects of the earth circuit may affect the telephone and telegraph circuits, though the earth current is practically negligible except in case of an accidental ground.

**86. Conditions of advantageous grounding.** A system in excess of 60,000 volts may well be grounded, unless absolute continuity of service is essential. A line connected as a part of a large system should be grounded. It will then be automatically disconnected and cannot subject the entire system to the delta voltage between line wire and ground. A cable system* should be grounded, as oscillations and transients are of common occurrence, and a ground in one part of the system may otherwise cause a breakdown in the insulation at some other point. To locate and repair a ground in a cable system is expensive, requiring considerable time.

**87. The ground† connection may be made** by connecting the neutral to a copper plate buried in charcoal; by connecting to a metal plate immersed in a nearby body of water; by connecting to metal work in contact with the earth or water; by driving iron pipes of about 1 in. (2.54 cm.) or so in diameter and 6 ft. (2 m.) length into the earth 6 ft. (2 m.) apart, and pouring salt water around them. To limit the short-circuit current, a resistance may be inserted in the neutral connection, though to secure one having the necessary resistance and carrying capacity is expensive. A reactance should not be used in the neutral as it may increase the probability of oscillations. The ground should be made at only one point of the system, at the power-house, as otherwise earth currents tend to flow and to disturb telephone and telegraph circuits in the vicinity of the line.

**88. Ungrounded systems‡ have the following advantages:** (a) an accidental ground does not shut down the system; (b) the earth may serve as a third conductor until the damage can be repaired; (c) an arcing ground may be cleared by the arcing ground suppressor; (d) under normal conditions, there is little effect on telephone and telegraph lines.

**89. Disadvantages of ungrounded systems are as follows:** (a) Though the neutral of the system should be at ground potential, experiment has shown that excessive voltage may exist between neutral and ground; (b) the insulation of the system must be designed to withstand the delta voltage, and therefore must have 1.7 times the insulation for the same factor of safety; (c) an arc to ground is in series with the line capacity, and therefore tends to set up destructive high-frequency oscillations; (d) any electrostatic unbalancing affects neighboring telephone and telegraph systems.

**90. Ungrounded systems should be used** where the voltage is moderate; where a shut-down would be a serious matter; where the apparatus may well withstand the full-line potential.

**91. Transformer connections§** may be either delta or star. Transformers connected in delta must be able to withstand the total voltage between lines, hence their cost is greater than for star-connected transformers. They are more reliable than the star-connected, for if one transformer is disabled the system will continue to operate connected open delta. Transformers connected in delta may be heated by the third harmonic circulatory current. The star connection affords an accessible neutral, and the transformers need be designed to withstand only 58 per cent. of the line voltage. There is no third-harmonic circulatory current possible, and any third-harmonic voltage does not appear on the line. If one transformer goes out, the system must either be operated single-phase, or be shut down, unless a spare unit is available. Voltage taps are easily brought out from the transformer winding in the star connection. See Sec. 6.

**92. Switching‖** a transmission line may give rise to transients causing

* See Bibliography 46.
† See Bibliography 63.
‡ Bibliography 67, 68.
§ Bibliography 23.
‖ See Bibliography 48, 49.

Digitized by Google

serious damage to line and apparatus. The matter is further complicated by the characteristics of the oil switches themselves. When the switch contacts approach each other on closing the circuit, small arcs of decreasing magnitude are set up between them. These may result in high frequency oscillations corresponding in period to the natural frequency of the transformer windings. In a three-phase switch the three contacts may not close at the same instant which further complicates the problem. Similar phenomena occur when the switch opens the circuit, the arcs between contacts increasing in magnitude. The maximum possible voltage rise as the switch opens is given by

$$e = i\sqrt{L/C} \qquad (27)$$

where $i$ is the current at the moment of break and $L$ and $C$ are the circuit inductance and capacity respectively. The voltage does not usually approach this limiting value as the arcs formed between the contacts introduce resistance which diminishes the voltage rise. The switch also absorbs some of the energy stored in the line. The voltage rise, under ordinary switching conditions, may not exceed the normal operating value more than from 50 to 75 per cent. The excessive rises in potential occur under short-circuit conditions, when the current may reach many times full-load value. Aluminum arresters and power-limiting reactances offer the best solution of the problem.

**93. High-tension and low-tension switching** are both extensively employed, there being no consensus of opinion as to which is more desirable. The following methods are used in switching on a substation.

(a) Connect the line to the high-tension bus at the generating station, and then switch the substation transformers.

(b) Connect substation transformers to the dead line, and then switch the line to the high-tension bus at the generating station.

(c) Connect the open line to the transformers at the generating station, switch these on the low side, and then connect the substation transformers at the end of the live line.

(d) Connect the substation transformers to the dead line and step up transformers and switch these latter on the low tension side.

(a) and (b) come under the classification of high tension switching and (c) and (d) low-tension switching. The reverse order may be followed, when switching off.

Transformer switching may result in abnormal current rushes, if the circuit is closed on a point of the e.m.f. wave, which does not correspond to the residual magnetic state of the transformer.

## POWER-FACTOR CORRECTION

**94. Power-factor correction*** may often be made on transmission lines, whereby the voltage regulation may be materially improved, the generating capacity increased and the copper losses reduced. This correction may be made by the over and the under excitation of synchronous apparatus at the receiving end of the line. When used for this purpose exclusively, such apparatus is called a synchronous condenser. This synchronous apparatus may be a part of the receiver and used for further distribution of power, or it may merely float on the end of the line, its sole function being to regulate the power-factor, or the voltage. As synchronous motors are not wound for voltages much in excess of 13,000 volts, they must be connected to the low sides of transformers if the line voltage exceeds this value. When the motor is installed solely to improve transmission efficiency, the cost of the power required by the motor plus its maintenance and fixed charges, must not exceed the cost of the power saved, and must be less than the interest on the cost of installing more copper. As the synchronous apparatus may fall out of step, or be damaged by surges or short-circuits, it is generally desirable to install copper, which will give greater reliability, and has a better scrap value.

When improved regulation is the result desired, the installation of synchronous apparatus may be justified regardless of the energy saving. Where large amounts of power are concerned, it is impracticable to install synchronous condensers to take care of the entire quadrature current, although they may be used for purposes of improved regulation.

* Bibliography 71–77 incl.

Digitized by Google

**95. Calculations for power-factor correction.** The per cent. quadrature current required for unity power-factor at the receiver may be determined from Fig. 41, or may be calculated for a three-phase system as follows:

$$I_1 = \frac{W}{3E} \tag{28}$$

$$I_2 = \frac{W}{3E} \tan \theta \tag{29}$$

where $I_1$ and $I_2$ are the energy and quadrature components of current respectively, $W$ is the power, in watts, at the receiver, $E$ is the voltage, from line wire to *neutral*, at the receiver, and $\theta$ is the angle between the current and voltage vectors. It will be noted, from Fig. 41 that it requires a much larger synchronous motor to bring the power-factor from 95 per cent. to 100 per cent., than it would require to bring it from 90 per cent. to 95 per cent. As a rule, it is not economy to install apparatus large enough to obtain the last 5 per cent.

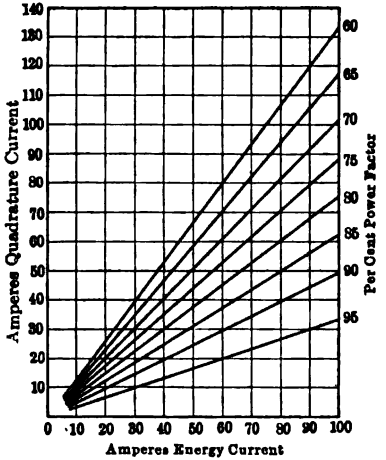

FIG. 41.—Energy and quadrature currents.

**96. Constant receiver voltage* may be obtained** by varying the excitation of the synchronous apparatus, either by use of an automatic regulator which acts on the exciter or by compounding, if the synchronous apparatus is a motor-generator or a rotary converter. When the variations in voltage are not severe, hand regulation may be employed. Machines cannot always be compounded to give constant voltage at all loads, though the condition of constant voltage may be approximated. As the voltage of a line may rise on open circuit to a value in excess of the generator voltage, due to the line charging current, the synchronous apparatus must be able to shift its phase from leading to lagging current. The power-factor being known, the quadrature current and the required capacity of synchronous apparatus may be determined by plotting Fig. 17 (Par. **28**) to a large scale. For more complete discussion consult the bibliography references.

## STRESSES IN SPANS

**97. Mechanical stresses** in a span are produced by: (a) the dead weight of the conductor, which acts vertically; (b) the weight of any ice, sleet, or snow that may cling to the wire; and (c) the wind pressure, which is assumed to act horizontally, at right angles to the line, and on the projected area of the conductor, and its sleet loads.

The weights of copper and aluminum conductors are given in Par. **99**. The weight of ice is 57 lb. per cu. ft., or 0.033 lb. per cu. in. and the weight of sleet and snow is somewhat less than this. For the average climate of the United States, a layer of ice 0.5 in. (1.27 cm.) thick is assumed to be the worst condition of loading, though in the mountainous regions, sleet may form to a greater thickness than this. The table in Par. **99** gives the ice and conductor loads with 0.5-in. and 0.75-in. layers of ice, for both copper and aluminum conductors.

* Bibliography 73, 75, 77.

Digitized by Google

The wind pressure is a function of the wind velocity and may be expressed by Buck's* formula

$$p = 0.0025V^2 \qquad \text{(lb. per sq. ft.)} \qquad (30)$$

Where $p$ is the pressure in lb. per sq. ft. and $V$ is the actual velocity of the wind in miles per hr. Fig. 42 shows the relation between velocity and wind pressure. Buck gives the following as the relation between actual velocity and that indicated at the Government observation stations.

| Indicated velocity... | 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 | 90 | 100 |
|---|---|---|---|---|---|---|---|---|---|---|
| Actual velocity..... | 9.6 | 17.8 | 25.7 | 33.3 | 40.8 | 48.0 | 55.2 | 62.2 | 69.2 | 76.2 |

Fig. 43 shows the wind pressure at different heights above ground, and Par. 99 gives the pressure for the various conductors and ice loads.

The resultant force acting on the conductor, is the vector sum of the horizontal and vertical forces shown in Fig. 44. The resultant loading for various conditions of component loading on line conductors is given in Sec. 4.

**98. The general span formulæ**, assuming that the span has the form of a parabola, and that the weight is uniformly distributed, are as follows:

$$t = \frac{S^2 w}{8d} \qquad \text{(lb.)} \qquad (31)$$

$$d = \frac{S^2 w}{8t} \qquad \text{(ft.)} \qquad (32)$$

$$l = S + \frac{8d^2}{3S} \qquad \text{(ft.)} \qquad (33)$$

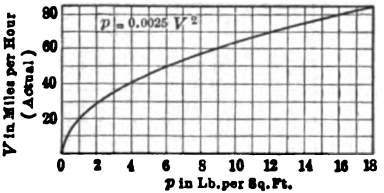

FIG. 42.—Wind velocity and pressure.

where $t$ is the horizontal tension in lb., $S$ is the span length in ft., $d$ is the sag in ft., $w$ is the weight in lb. per ft. of the conductor plus the sleet or snow, and $l$ is the length of the conductor in ft. The total tension $T$ in the conductor at the support, is the sum of the horizontal component $t$, and the vertical component due to the dead load.

$$T = t + wd \qquad \text{(lb.)} \qquad (34)$$

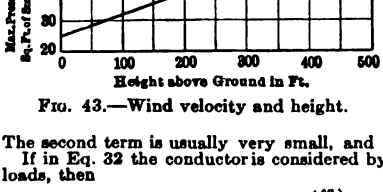

FIG. 43.—Wind velocity and height.

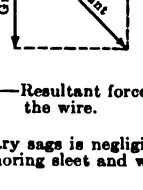

FIG. 44.—Resultant force on the wire.

The second term is usually very small, and for ordinary sags is negligible.

If in Eq. 32 the conductor is considered by itself, ignoring sleet and wind loads, then

$$d = \frac{S^2\left(\frac{w}{A}\right)}{8\left(\frac{t}{A}\right)} = \frac{S^2 W}{8F} \qquad \text{(ft.)} \qquad (35)$$

where $W$ is the weight of the conductor per ft. of length and for 1 sq. in. cross-section, and $F$ is the tension in lb. per sq. in. The required deflection may then be determined for the allowable unit stress.

NOTE: Class A loading = dead load + 15.0 lb. per sq. ft. wind pressure. $E$ = modulus of elasticity, in.-lb.
Class B loading = dead load + 0.5 in. ice + 8.0 lb. wind pressure. $A$ = conductor area.
Class C loading = dead load + 0.75 in. ice + 11.0 lb. wind pressure. $EA$ = product of modulus of elasticity and conductor area.

RULE.—To find stress in lb. on wire of given span and deflection, multiply numbers in column answering to span and deflection by the weight per ft. of wire.

Digitized by Google

**102. Calculation of horizontal stress.*** The foregoing tables give the factors by which the weight per ft. of conductor may be multiplied, in order to determine the horizontal stress in the span. Values are given up to 200 ft. (61 m.) spans, and to 20 per cent. deflections. For any span greater than 200 ft. (61 m.) the table may still be used, if it be remembered that for a given percentage deflection, the stress is proportional to the span. Thus for a 1,500-ft. (4.57 m.) span having 2.0 per cent. deflection, and a total weight of 0.5 lb. per ft. (1.64 lb. per m.) the horizontal stress will be (from 150-ft. span)

$$t = 938 \times 10 \times 0.5 = 4690 \text{ lb.}$$

In the same way, the length of this span wire (Par. **101**) will be (with 150-ft. span)

$$l = 150.16 \times 10 = 1501.6 \text{ ft.}$$

The tables were computed from formulæ given in Weisbach's "Mechanics of Engineering," page 297 (seventh American edition, translated by Eckley B. Cox, A.M.)

$S \times W$ = horizontal stress in wire at centre of span (lb.) (36)

$$S = y^2/2x + x/6 \text{ (ft.)} \quad (37)$$

$$l = y[1 + (2/3)\,(x/y)^2] \text{ (ft.)} \quad (38)$$

$$x = 3S - \sqrt{9S^2 - 3y^2} \text{ (ft.)} \quad (39)$$

$$y = \sqrt{(3yl - 3y^2)/2} \text{ (ft.)} \quad (40)$$

where $y$ = one-half the span.
$l$ = one-half the length of the span wire.
$x$ = deflection at centre in same units as $y$.
$w$ = dead weight per ft. of wire.

**103. Temperature variations** will change the length of the span, and as the sag and tension are very sensitive to changes in the length of span, the effect of change of temperature must be considered. With a change of tension, the length of the wire will be changed, due to stretching or contracting. As stretch and temperature change are inter-related and occur simultaneously, their combined effect must be determined. As an analytical calculation is difficult to make, the solution is better determined by graphical methods. For every degree fahr. change in temperature, the length of unstressed copper will change 0.00096 per cent., and of aluminum 0.00128 per cent. The following table gives stress and temperature data for both copper and aluminum conductors.

**104. †Properties of conductor materials**

| Copper | Ultimate strength per sq. in. | Elastic limit | Mod. elasticity, $E$ | Coef. expansion, $\theta$ |
|---|---|---|---|---|
| Solid, soft-drawn. | 32–34,000 | 28,000 | 12,000,000 | 0.0000096 |
| Solid, hard-drawn. | 50–55–57–60,000 | 30–32–34–35,000 | 16,000,000 | 0.0000096 |
| Stranded, soft-drawn. | 34,000 | 28,000 | 12,000,000 | 0.0000096 |
| Stranded, hard-drawn. | 60,000 | 35,000 | 16,000,000 | 0.0000096 |
| Aluminum Stranded..... | 23–24,000 | 14,000 | 9,000,000 | 0.0000128 |

**105. The maximum stress** in a span occurs when it has its greatest loading of ice or sleet, minimum temperature, and maximum wind velocity blowing at right angles to the line. The loading usually assumed is 0.5-in. layer of ice at −20 deg. fahr. (−29 deg. cent.) and a wind pressure of 8 lb. per sq. ft. (at a velocity of about 57 miles per hr.) The load under these conditions may then be determined from Par. **99**, and the stress from Par. **100**, or calculated from Eq. 31, Par. **98**.

**106. Example of stress-sag calculation.** Problem: Required to find the proper sag for a 600-ft. span of No. 0000 hard-drawn solid copper, at

* From "Wire in Electrical Construction" by John A. Roebling's Sons Co.
† Report of the Joint Committee on Overhead Construction, N. E. L. A.

Digitized by Google

maximum (summer), minimum (winter-loaded), and stringing (unloaded) temperatures.

From Par. **99** for 0.5-in. ice, and 8 lb. per sq. ft. wind pressure, the total load per lin. ft., $w$, is 1.575 lb. The allowable tension, $t$, is 4,150 lb. (corresponding to 25,000 lb. per sq.in.). The sag may be calculated from Eq. 32, Par. **98**. $d = [(600)^2 \times 1.575]/(8 \times 4{,}150) = 17.08$ ft. at the assumed minimum temperature.

This is the sag under ice load at $-20$ deg. fahr.

The maximum sag will occur at $+120$ deg. fahr., the assumed maximum temperature, with no load other than the conductor itself and no wind.

To determine this sag first consider that all the stress is removed from the conductor, and determine its length under this condition.

The change of length due to removing the load, $\Delta l = \dfrac{tl}{EA}$ (41)

In this expression, $t$ is the tension in lb., $l$, the length in ft., $E$, the modulus of elasticity, in-lb., $A$, the cross-section of the conductor, in sq. in. Values of $EA$ are given in Par. **99**.

The original length, from Eq. 33, Par. **98**, is $l_1 = 600 + [8 \times (17.08)^2/(3 \times 600)] = 601.297$ ft. $\Delta l = 4{,}150 \times 601.297/2{,}659{,}000 = 0.939$ ft. The span, then, if all stress were removed, would have the hypothetical length at $-20$ deg. fahr., $601.297 - 0.939 = 600.358$ ft. This often results in a value less than the span length. At zero deg. fahr., the length would be given by

$$l = l_0(1 + \alpha t') \qquad (42)$$

Where $l_0$ is the length at zero deg. fahr. $\alpha$ is the coefficient of expansion, $t'$ is the temperature deg. fahr. $l_0 = 600.358/[1 + 0.0000096 \times (-20)] = 600.473$ ft. $c_0 = \sqrt{[3 \times 600(600.473 - 600)]/8} = 10.31$ ft. (Eq. 33, Par. **98**.)

**107. To obtain the sag at zero deg. fahr.**, no ice and no wind load, the sag-stress curve $ab$ should first be plotted (Fig. 45), having $w = 0.641$ lb. per ft., weight of conductor with load removed (Par. **99**). The table of Par. **100** is very convenient for this purpose. The sags for different tensions are then calculated, by finding, first, the length from Eq. 41, and then the sag from Eq. 32, Par. **98**. These values are now plotted (curve $cd$); where this curve intersects the sag-stress curve $ab$ will be the sag at zero deg. fahr., when the conductor has no load other than its own weight.

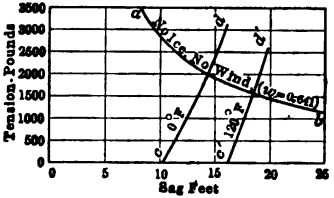

FIG. 45.—Stress-sag curves.

Thus, at a tension of 3,000 lb., $l_1 = 600.473 + [(600.473 \times 3{,}000)/2{,}659{,}000] = 600.473 + 0.678 = 601.151$ ft. (from Eq. 41). $d = \sqrt{[1{,}800(601.151 - 600)]/8} = 16.09$ ft. (from Eq. 33, Par. **98**). From the intersections, sag at zero deg. fahr. = 14.4 ft. and tension at zero deg. fahr. = 2,000 lb.

**106. The sag at another temperature may be found** by increasing the abscissa by a distance, determined from Eq. 42 and Eq. 33, Par. **98**. Thus, to find the sag and tension for 120 deg. fahr., $l = 600.472\,(1 + 0.0000096 \times 120) = 601.163$ ft. at 120 deg. fahr. and zero stress, $d = 16.18$ ft.

The sag and stress should then be computed as in Par. **107**, and a new stretch line $c'd'$ plotted. The maximum sag (assumed at 120 deg. fahr.) occurs where $c'd'$ cuts $ab$. It is equal to 18.5 ft., and the corresponding tension 1,560 lb.

**109. Data used when stringing.** A set of stretch curves for several temperatures should be furnished the foreman in charge of stringing the wire, in order that he may adjust the sag, or tension (by means of a dynamometer) to their proper values for the temperature at the time of stringing. It must be remembered that the temperature of the wire, when the sun is shining, may be several degrees higher than that of the surrounding air.

**110. With the supports at different levels**, the line forms a catenary, the lowest point of which is no longer midway between supports. The curve can, however, be prolonged until it reaches a point which is at the same

Digitized by Google

level as the higher support (Fig. 46) and the distance $x_1$ to the lowest point of the catenary will be equal to half the assumed span, $S'$, and may be computed.

$$x_1 = \frac{S}{2} + \frac{ht}{wS} \quad \text{(ft.)} \qquad (43)$$

$$x_1 = S\,\frac{\sqrt{d}}{\sqrt{d-h}+\sqrt{d}} \quad \text{(ft.)} \qquad (44)$$

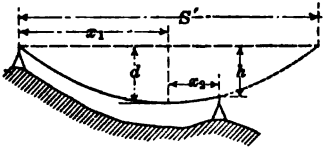

FIG. 46.—Supports at different levels.

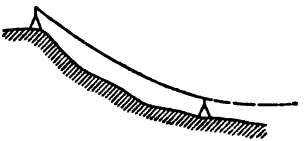

FIG. 47.—Condition for upward pull at lower support.

where $S$ is the horizontal distance between supports, $d$ the sag measured from the higher support, $t$ the tension in the wire in lb. at the higher support, $w$ the weight in lb. per unit length, $h$ the difference in height of supports, all distances expressed in ft.

Eq. 43 is useful when the span and the allowable stress are given; and Eq. 44 when the span and sag are given. Eq. 43 is correct to within 2 to 4 per cent. when neither the sag nor difference in height of supports exceeds 15 per cent. of the span. Eq. 44 has an error of less than 1 per cent. under these conditions.

The sag $d$ may be computed,

$$d = d'\left(1+\frac{h}{4d'}\right)^2 \quad \text{(ft.)} \qquad (45)$$

where $d'$ is the sag as determined by Eq. 32 for the same span, $S$, and the same loading.

also

$$x_2 = \frac{S}{2}\left(1-\frac{h}{4d'}\right) \quad \text{(ft.)} \qquad (46)$$

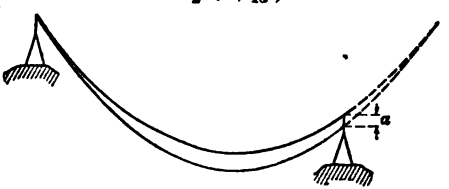

FIG. 48.—Error introduced by assuming constant equivalent span.

Having determined the distance $x_1$, the span may then be treated like a span $S'$, where $S' = 2x_1$. From Eq. 46 if $h/4d'$ is greater than unity, the vertex of the line will lie outside the span, and there will be an upward pull on the insulator. This is shown in Fig. 47 and the span should be so designed that this condition does not occur.

Load and temperature changes may be computed as in Par. **107** and **108**, but a certain error is introduced in assuming that the length of equivalent span remains unchanged. Except for accurate work, this error is negligible. The error increases or decreases with the difference in height of supports by an amount, $a$, Fig. 48. For accurate work, however, the length of line in the span may be computed from Eq. 33 knowing $x_1$, $x_2$ and $d$ (Fig. 46) and the effects of changes of load and of temperature may also be computed. The new distance $x_2$ is determined and the new equivalent length of span found.

**111. The Thomas chart* for sag and stress determinations** is based on the following: Imagine a given span to be reduced to a length of 1 ft. without changing the shape of the curve. The percentage sag will remain the same, but the sag, stress and length of wire will be reduced in direct proportion. The stress for a definite sag is proportional to the weight per unit length of the wire including ice and wind loads. The curves, Fig. 49, show the relation

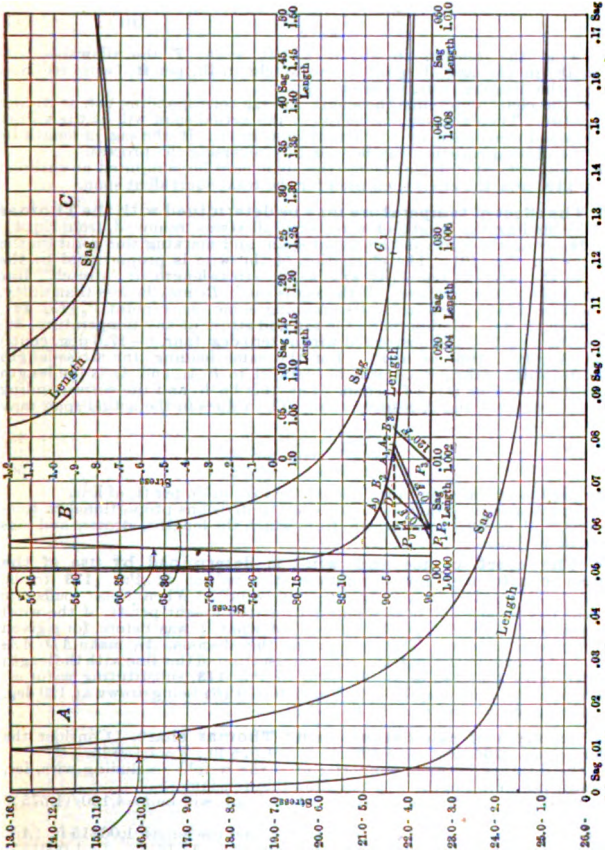

FIG. 49.—Thomas chart.

between sag, length of wire and stress, for a 1-ft. span loaded uniformly with 1 lb., and are based on the equation of the catenary. Three sets of curves, *A*, *B*, and *C*, are given, all plotted to different scales. Curve, *A*, is good for sags from 2 to 15 per cent.; curve *B*, for sags less than 2 per cent.; curve *C*, for very large sags, being especially useful for spans on steeply inclined slopes

*See Bibliography 88.

Digitized by Google

The chart in Fig. 49 is too small for accurate work but the data from which the curves were plotted may be obtained from the original paper (Bibliography 88).

**112. Use of the Thomas chart.** By means of these curves, the sag, stress, and length of any span may be easily determined. Divide the allowable stress in the wire, by the span and weight per unit length.

$$t = \frac{T}{w \times S} \quad \text{(lb.)} \qquad (47)$$

where $t$ is the tension in lb. in a 1-ft. span; $T$ the allowable tension in lb. in the actual span; $w$ the weight in lb. per ft. (wire, ice and wind); $S$ the distance in ft. between supports.

From the chart, determine the length and sag corresponding to $t$, as $A_1$ and $C_1$ (Fig. 49). Then the sag and length in the actual span will be the values just obtained multiplied by the actual span in ft. If the sag, or length be given, the other quantities may be found by reversing the process.

With supports at different levels the span may be computed as outlined in Par. **110**, and the chart then used for the total equivalent span.

**113. The effect of temperature may be determined with the Thomas chart** by finding the length of wire, with all stress removed, from Eq. 41, Par. **106**, using the stress in the *actual* span, and marking this point on the chart (as $P_1$, Fig. 49). The elongation of the wire is proportional to the stress, so the straight line $P_1A_1$ will be the stress-length or "stretch" line for this load and temperature. If the sag is small, $P_1$ may be less than unity, but the line may be drawn by determining some other point $P_0$ (Eq. 41), and drawing $P_0A_0$. To determine the sag and stress at any temperature, determine the length of the unstressed wire at zero deg. fahr. (−17.8 deg. cent.) by Eq. 42, Par. **106**, as at $P_2$. For the same loading, the stress-length line at zero deg. fahr., $P_2A_2$, will be parallel to $P_1A_1$, and $A_2$ is the length at zero deg. fahr. of the 1-ft. span. Let this be $l_1$, and the corresponding stress and sag be $t_1$ and $d_1$ respectively. The values in the actual span may then be found.

$$\text{Actual length} = Sl_1 \qquad (48)$$
$$\text{Actual stress} = St_1w' \qquad (49)$$
$$\text{Actual sag} = Sd_1 \qquad (50)$$

Where $S$ is the actual span in ft., and $w'$ the load in lb. per ft. of line.

The length axis may then be marked off in divisions proportional to temperatures, and parallel lines drawn, from which the lengths, stresses and sags may be determined.

**114. The effect of ice and wind is determined by use of the Thomas chart** as follows: Suppose the values in Par. **113** to be computed for maximum loading (ice and wind). When these loads are removed, the weight per ft. is reduced to $w$ (the weight per ft. of the wire) and the stretch in the wire will be $w/w'$ of what it was before, for a given stress in the 1-ft. span. Therefore, along the abscissa, $A_2$, make $AD/AA_2 = w/w'$ and draw $P_2B_2$ through $D$. The intersection of this line with the length curve will give the results as obtained in Par. **113**, substituting $w$ for $w'$. The temperature lines may be found as before. $P_2B_2$ being drawn at 120 deg. fahr. (49 deg. cent.) and parallel to $P_2B_2$.

**115. Example of calculation, using Thomas chart.** Consider the problem of Par. **106** where $S = 600$ ft., $w' = 1.575$ lb., $T = 4{,}150$ lb.

$S$ is the distance between supports; $w'$ is the weight (including wire, ice, and wind) per unit length; $T$ is the allowable tension.

The tension in a 1-ft. span, having a 1-lb. load, will be $t = 4{,}150/(1.575 \times 600) = 4.395$.

From curve $B$ the sag will be 0.0286 ft. ($C_1$) and the length 1.00215 ft. ($A_1$). The true sag and length will be $S = 600 \times 0.0286 = 17.16$ ft. $l = 1.00215 \times 600 = 601.290$ ft. The length unstressed, may be found (Eq. 41, Par. **106**).

$$\Delta l = (1.00215 \times 4{,}150)/2{,}659{,}000 = 0.00156 \text{ ft.}$$
$$l_1 = 1.00215 - 0.00156 = 1.00059 \text{ ft.}$$

A line $P_1A_1$ is drawn from $P_1$ (length = 1.00059) to $A_1$, the original point on the length curve. The length at zero deg. fahr. is found from Eq. 42, Par. **106**. $l_0 = 1.00059/[1 + 0.0000096 \times (-20)] = 1.00078$ ft. A line $P_2A_2$ is drawn

Rules for Using Chart
l = length of span in feet.
T = max. allowable tension in lbs. per sq. in.
K = ratio of total force on wire to weight of wire when under max. tension.
t = temperature in F. corresponding to max. tension.
t₀ = temperature at which wire is to be strung.
To Find:
T₀ = tension at which wire is to be strung.
D = deflection at stringing temperature.
Procedure:
1. On the straight edge of a strip of a paper mark a reference point A.
2. Place the edge of this strip along the temperature scale and lay off above A the point (B) at a distance t − t₀ from A.
3. Next place the strip along the ordinate erected at T₀ on tension scale, and make the point A coincide with the curve marked with the number equal to K₀ l.
4. Mark on the strip the point (C) at which the heavy straight line marked with the value of the modulus M crosses the edge of the strip.
5. Slide the strip towards the left, keeping the point C on the modulus line, until the point B coincides with the curve marked with the number equal to l. The abscissa of the corresponding point on this curve gives the tension T and the ordinate of this point the percent deflection p; the deflection in feet is then
D = pl/100

Wind pressure — 8 lbs. per sq. ft. — None
Max. allowable tension (T₀) — 19000 lbs. — 20000 lbs.
Minimum temperature (t₀) — 0°F — −10°F
Stringing temperature (t) — 70°F — 70°F
Then:
K₀ — 11.6 — 1.99
K₀l — 2320 — 2980
Stringing tension (T) — 1290 lbs. — 15000 lbs.
Percent deflection (p) — 2.27 — 4.52
Deflection (D) — 4.54 — 69.4

FIG. 50.—Pender and Thomson chart.

Digitized by Google

(where $P_3 = 1.00078$) parallel to $P_1A_1$. At zero deg. fahr., with wind and ice loads,

| | Chart | Actual |
|---|---|---|
| Length | 1.00224 ft. | $600 \times 1.00224 = 601.344$ ft. |
| Stress | 4.2 lb. | $600 \times 4.2 \times 1.575 = 3{,}965$ lb. |
| Sag | 0.0295 ft. | $600 \times 0.0295 = 17.70$ ft. |

To find the length, stress and sag when the loads are removed. At zero deg. fahr., no ice, and no wind, $w = 0.641$ lb. At the stress as now shown on the chart of 4.2 lb., the stretch will be $(1.00224 - 1.00078)0.641/1.575 = 0.00059$, and the length $1.00078 + 0.00059 = 1.00137$. Draw $P_2B_2$ through 1.00137 at the 4.2 lb. ordinate (at $D$). Graphically

$$AD/AA_2 = 0.641/1.575$$

Then, at zero deg. fahr., no ice or wind,

| | Chart | Actual |
|---|---|---|
| Length | 1.0015 ft. | $600 \times 1.0015 = 600.90$ ft. |
| Stress | 5.1 lb. | $600 \times 5.1 \times 0.641 = 1{,}960$ lb. |
| Sag | 0.0244 ft. | $600 \times 0.0244 = 14.6$ ft. |

The unstressed length at 120 deg. fahr. is found from Eq. 42, Par. **106.** $1.00078(1 + 120 \times 0.0000096) = 1.00193$ ft. At $P_3(l = 1.00193)$ draw $P_3B_3$ parallel to $P_2B_2$. Then, at 120 deg. fahr.,

| | Chart | Actual |
|---|---|---|
| Length | 1.00234 ft. | 601.40 ft. |
| Stress | 4.1 lb. | 1,577 lb. |
| Sag | 0.031 | 18.6 ft. |

These results check very closely with those already obtained using Fig. 45. The differences are due to errors in reading the charts, and to the assumption of a parabola rather than a catenary.

The distance $P_1P_3$ may be subdivided proportional to temperatures, and results may be found by drawing stretch lines parallel to $P_3B_3$.

**116. Pender and Thomson tension and deflection chart.*** By means of this chart, Fig. 50, the sag and deflection may be found directly. The rules for its use, together with examples, accompany the chart. The values of $K_e$ in the examples given are slightly different from the values in Par. **99.** The problems are worked in lb. per sq. in.

**117. The horizontal stresses in adjacent spans should be equal** to minimize the longitudinal pull on the support. In level country and with equal spans this may be easily accomplished by making equal sags at a given temperature. Unequal spans can be equalized only at one temperature which should be the average temperature. Suspension insulators, by deflecting, tend to equalize unbalanced stresses. For equal horizontal stresses with the supports at different levels, the wire in each span should form portions of equal catenaries (parabolas assumed) as shown in Fig. 51. This condition holds for but one temperature.

FIG. 51.—Balanced horizontal stresses.

**118. Short-circuit due to unbalanced ice loads.†** Ice loads on wires may drop from all but one span. If suspension insulators are used and the lines are arranged in a vertical plane, this span, aided by the longitudinal deflection of the suspension insulators, will sag heavily and the adjacent spans will be drawn up, as shown in Fig. 52. The phase wires may readily ap-

* See Bibliography 20. † See Bibliography 90.

Digitized by Google

proach within easy arcing distance of one another or even touch in all three spans, thus causing a short-circuit. Also, if one wire alone loses its ice load its whipping up may cause short circuit. This may be partially overcome by the use of shorter spans, more anchor towers, or better, by offsetting the middle conductor, thus making an isosceles triangle arrangement (see Fig. 64, isosceles triangle).

## STRENGTH OF SUPPORTING MEMBERS

**119. Insulators and pins** must be designed to withstand the weight of conductor and any ice, sleet or snow load; the wind pressure acting on the conductor, and any other transverse force produced by a change in direction of the line; the longitudinal force due to unbalanced horizontal stresses in adjacent spans; the longitudinal stress occasioned by the breaking of a line conductor. It is desirable that they withstand a stress equal to the elastic limit of the conductor, when exerted in any direction in a plane perpendicular to the axis of the pin.

**120. The cross arms** must be designed to withstand the resultant of the forces of Par. **119**, and the dead weight of insulators and attachment. In addition, the cross arms must be secured to the pole so that they will not be wrenched loose by the turning moment which follows the breaking of one or more conductors on the same side of the pole. The results of "Strength Tests of Cross Arms," made by T. R. C. Wilson, are published in U. S. Government Forest Service Circular 204.

**121. The supporting structure** must be designed to bear the compressive stress, due to its own weight and that of conductors, loads, insulators, cross arms and attachments; the transverse forces due to wind on conductors and supporting structure and also those occasioned by change in direction of the line; the longitudinal stresses due to unbalanced horizontal stresses in adjacent spans; stresses caused by the breaking of one or more conductors.

Wooden, steel, or concrete poles, designed to withstand the horizontal forces, will have the necessary compressive strength to bear vertical loads. With towers of the light wind-mill type, this matter should be carefully considered. Where extreme rigidity at small expense is desired, the structure must be made of many light members, resulting in a more complicated tower, and a shorter life, due to the greater proportionate corrosion. A less rigid tower made of fewer but heavier members will frequently answer the purpose, will be less expensive and of longer life.

**122. The transverse force due to the wind** on the conductors should be assumed as 8 lb. per sq. ft.* of the projected conductor and ice area. A 0.5-in. (1.27 cm.) layer of ice is usually assumed. Values of the resulting pressure may be found in Par. **99**. The pressure on the pole or tower may be

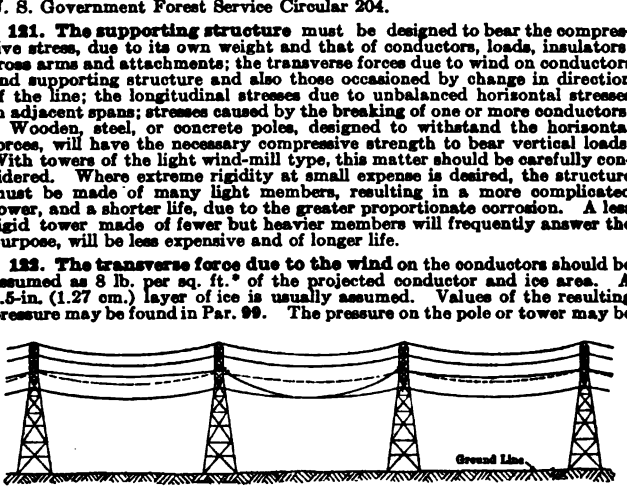

FIG. 52.—Ice loading on single span.

assumed to be 13 lb. per sq. ft. on one and one-half times the projected area of latticed structures. (Also see Sec. 12, Par. **166**.) The overturning moment may be greater without the ice load. Both conditions should be calculated. The stress due to an angle in the line may be readily computed by a simple resolution of the maximum stresses already calculated for the spans. The longitudinal forces due to unbalanced horizontal stresses in adjacent spans, should be small in a well-designed line, and may be determined if the stresses in each span at different temperatures are known. There is some question as to how many conductors may be assumed to be broken at one time. If

* Report of the Joint Committee on Overhead Line Construction, N. E. L. A.

a line is carefully strung with no kinks or abrasions in the wires, and if the ends of the insulator clamps are well rounded, there is small chance of a line conductor breaking under ordinary load conditions. As an extra precaution, however, anchor towers are used at frequent intervals, and are so designed as to safely withstand the simultaneous breaking of several conductors. Where suspension insulators are used, the insulator string is thrown in the unbroken side of the span, hence the increased sag decreases the ultimate pull. The force due to the jerk at the time of breaking is quite severe, and no reduction in the allowable stress should be made even if suspension insulators be used. The line structures should have a factor of safety of from 2 to 4, according to the importance of the line, the assumptions made in the design, and to the local conditions.

**123. A wooden pole** should be a cubic parabola, to use the material to the best advantage. As this would be impractical, a truncated cone, having the diameter of the top two-thirds of that of the bottom, is the best approximation. With this shape the pole will break theoretically at the ground line.

The allowable horizontal pull, $P$, on the pole may be calculated

$$P = \frac{T}{n}\frac{\pi d_1^3}{32l} \quad \text{(lb.) for a round pole.} \qquad (51)$$

$$P = \frac{T}{n}\frac{d_1^3}{6l} \quad \text{(lb.) for a square pole.} \qquad (52)$$

assuming that $d_1$, the ground diameter in inches, is one and one-half times the top diameter. In these formulæ $n$ is the factor of safety, $l$ the length of the pole in inches, and $T$ the tensile strength or modulus of rupture of the pole material, values of which are given in Sec. 12, Par. **104**. The factor of safety should be at least 5 or 6 for wood.

**124. The stresses in steel poles** cannot readily be calculated due to the complications introduced by lattice work, cross bracing, etc., and the engineer is more or less dependent upon actual tests and manufacturers' guarantees for data relative to the load that a given structure may be expected to carry safely. Steel poles, for the same weight and material, have much less torsional strength than steel towers. Although they may be satisfactory under normal conditions of balanced load, their factor of safety may be much reduced if one or more wires on the same side of the pole should break.

**125. The stresses in concrete poles** may be computed approximately, knowing the moment of inertia of the top and bottom sections, the cross-section and tensile strength of the reinforcing steel, and the compressive strength of the concrete. Up to the present time, however, very little has been done along this line, and purchasers and manufacturers have been dependent upon actual tests of full-sized poles. The usual mixture of Portland cement (1 : 2 : 4, cement, sand and gravel) has a compressive strength after 7 days of 900 lb.; after 1 month, 2,400 lb.; after 3 months, 3,100 lb.; after 6 months, 4,400 lb. all in lb. per sq. in.

**126. Stresses in guys and anchors** may be readily computed if the magnitude, direction, and point of application of the resultant force acting on the pole are known. The position of the anchor is determined, and the stress in the guy and anchor can be calculated by the well-known laws governing the composition and resolution of forces. The table in Sec. 4 gives the diameters, strengths and weights of 7-strand galvanised steel wire, such as would be used for guys.

**127. The stresses in towers** may be computed by the well-known laws of statics. As steel fails in compression rather than in tension the compressive strength of the long unsupported members should be carefully checked by the well-known column formulæ. The ratio of $l/r$, where $l$ is the length of the unsupported compression member, and $r$ is the radius of gyration of its section, should seldom exceed 150. R. D. Coomba* shows, in the following table, that by using a different angle iron of less cross-sectional area the strength of the main compression members is nearly doubled. This should not be carried too far, however, if a reasonable life is expected. It is

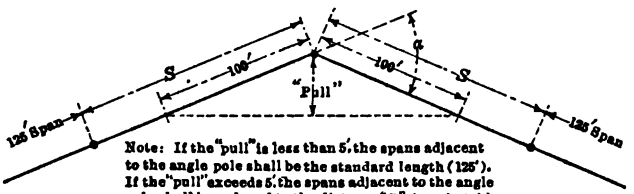
* Letter to *Elect. World*, Vol. LVII (1913), p. 544.

Digitized by Google

generally conceded that $\frac{1}{4}$ in. for the legs and $\frac{1}{16}$ in. for the secondary members should be the minimum permissible thicknesses of metal.

| Section | Area, sq. in. | Length, ft. | $l/r$ | Breaking strength, lb./sq. in. | Total breaking strength, lb. |
|---|---|---|---|---|---|
| 4 in. by 4 in. by $\frac{1}{4}$ in. angle. | 5.44 | 13 | 202 | 12,000 | 65,200 |
| 5 in. by 5 in. by $\frac{1}{16}$ in. angle. | 5.31 | 13 | 159 | 16,000 | 85,000 |
| 6 in. by 6 in. by $\frac{1}{16}$ in. angle. | 5.06 | 13 | 131 | 20,000 | 101,200 |

**128. Location of poles and side guys** may be determined by use of the table given with Fig. 53. The term "pull" refers to the deviation of the line and is equal to the distance from the pole to the straight line joining points on the line 100 ft. each side of the pole.



Note: If the "pull" is less than 5', the spans adjacent to the angle pole shall be the standard length (125'). If the "pull" exceeds 5', the spans adjacent to the angle pole shall be reduced to the distance "S" given in table.

| Angle α | "Pull" in Feet | Span S | No. of 6000 Lb. Side Guys | | |
|---|---|---|---|---|---|
| | | | 1 Arm 6 Wires | 2 Arms 12 Wires | 3 Arms 18 Wires |
| Less than 6° | Less than 5' | 125' | None | None | None |
| 6°-11° | 5'-10' | 115' | None | 1 | 1 |
| 11°-15° | 10'-13' | 105' | 1 | 1 | 1 |
| 15°-22° | 13'-19' | 95' | 1 | 1 | 2 |
| 22°-30° | 19'-26' | 85' | 1 | 1 | 2 |
| Over-30° | Over-26' | 75' | 1 | 2 | 2 |

FIG. 53.—Location of side guys.

**129. Flexible towers*** are used with a view to decreasing the line cost; their design is based on the fact that with equal spans and sags on both sides of the tower, the stresses in the direction of the line are balanced. The towers are not intended to carry longitudinal stresses but are designed to withstand any transverse stresses that may occur. They are held in position by the conductors, if pin insulators are used. When suspension insulators are used, a heavy steel galvanised ground wire is necessary to keep the towers in position. If a conductor breaks, the tower will deflect until the increased sag in the conductors and ground wire on the other side of the pole compensates for the unbalanced forces due to breaking. The towers should be designed to deflect from 12 in. to 24 in. without being permanently deformed. The unbalanced pull will not only be taken up by the tower at which the break occurs, but will be gradually absorbed by the other structures in the line. If a tower is actually pulled over, it is not a very serious matter because of its low initial cost, and ease with which another may be erected. About every mile there should be an anchor tower. Methods of computing the deflections and stresses in flexible towers have been published (see Bibliography 91 and 99). Such towers should be designed to carry from $\frac{1}{16}$ to $\frac{1}{8}$

* See Bibliography 91, 99.

Digitized by Google

the load for rigid towers and with this load should not be stressed beyond the elastic limit.

**130. Anchor towers,** when used in connection with flexible towers, should be designed to withstand the stress produced by the breaking of all the conductors on one side, even when the line is loaded under the most unfavorable conditions. Under these circumstances, there should be no yielding of the foundations, and the tower should not be stressed beyond the elastic limit. With a line constructed entirely of rigid towers, these conditions may be somewhat modified, as the intermediate towers themselves are designed to take care of one or two broken conductors.

## FUNDAMENTAL CONSIDERATIONS OF LINE CONSTRUCTION

**131. The line location** should in general be direct. Detours are often necessary, to avoid sections subject to severe lightning, to avoid country that may be inaccessible, to avoid swamps or hills that will make the construction difficult and costly. It may be necessary to pass near towns or villages where connected load may be profitable.

The most direct right of way cannot always be obtained at a reasonable figure. County plat maps or U. S. Topographical Survey maps should be carefully studied with special reference to the villages along the route, the proximity of roads, hence accessibility, and the topography that will permit standard structures and spans. When the location is roughly determined, a small surveying party should go over the route, make a profile, locate swamps, streams, railroads, other power, telephone or telegraph lines, and should note the character of ground and probable location of supports. Profiles should be made 100 ft. on each side of the centre line, as well as at the centre line, since a supporting structure might be advantageously located a short distance from the centre, if an abrupt change in profile made an increased height of structure necessary to secure the proper clearance.

**132. A private right of way** is necessary for most high-voltage transmission lines, as the risk to life and property from high voltages is too great to permit circuits to be carried along highways. The width should be so chosen that no tree or other object located outside the right of way can fall across lines. Where very tall trees do occur, they should be bought and removed. It is advantageous to secure the right of way near a highway, as the construction materials can be easily hauled to the tower locations. The line will also be more accessible for repairs, and patrolling is facilitated. Where the line must pass over private property, if possible it should follow the division lines.

**133. The proper form of contract should be executed,** when the consent of the proper parties is obtained. In many cases, as in sparsely settled districts, the land may be bought outright. The best practice, however, is to acquire perpetual right under easement, or for a term of years, with the right to renew the contract at the expiration of this time. Legal questions of importance should be settled by counsel. (Also see Bibliography 113–115 incl.)

**134. The conductor material** will be either copper or aluminum and the relative advantages and disadvantages of these are described in Par. **44** to **47** incl.

**135. The spans for any line will usually vary in length.** For level or undulating country a standard span, ranging from 100 to 800 ft. may be used. In hilly or broken country the support must be erected at advantageous points regardless of the varied lengths of spans that may result. With increased length of span, the number of structures and insulators (hence maintenance charges) is decreased, but the height of tower is increased. The cost of the tower may vary as the cube of the height. Other things being equal, the span should be so selected that the total line cost is a minimum. (See Par. **224.**)

**136. Extra long spans must be anchored** at each end. To secure sufficient tensile strength in the insulator, it is often necessary to connect a number of strings of suspension insulators in parallel. In order that each string may take its own share of the load, a *strain yoke* (Fig. 32) is used.

**137. The conductor spacing** should be such that the wires cannot swing within arcing distance of one another in the span. When suspension insulators are used, the wires at the insulators should not be able to swing

Digitized by Google

within arcing distance of the pole or tower. Allow a 45-deg. deflection from the vertical for copper and 60-deg. deflection for aluminum under the worst conditions of loading. Assuming that one of the phase conductors hangs vertical and that the other swings to the above angle, no two conductors must come within arcing distance of each other. Fig. 54* shows the usual spacings employed.

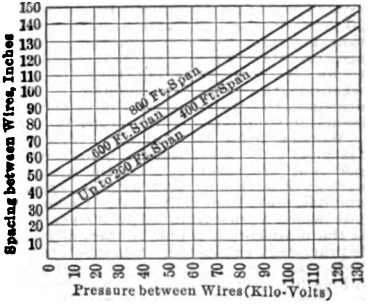


FIG. 54.—Approximate conductor spacing.

**138. Weighted conductors.** Where small conductors are used with suspension insulators it may be impracticable to increase the spacing by an amount sufficient to prevent the wires swinging more than 60 deg. By hanging a weight on the end of the insulator string, the maximum swing may be kept within this limit. The table in Par. **139**, presented by H. W. Buck,† gives the necessary weight per ft. of conductor to bring the deflection to 60 deg. Such weights also tend to prevent the propagation of mechanical waves longitudinally.

**139. Deflections and counterweights at various wind pressures**

| Size conductor A.W.G. | Wind pressure lb. per sq. ft. | Angular deflection without weight | Auxiliary weight per ft. conductor necessary for 60 deg. deflection |
|---|---|---|---|
| Stranded copper | | | |
| 4 | 15 lb. | 66 deg. | 0.041 lb. |
| 3 | 15 lb. | 63 deg. | 0.028 lb. |
| 2 | 15 lb. | 60 deg. | 0.000 lb. |
| Stranded aluminum | | | |
| 2 | 15 lb. | 81 deg. | 0.156 lb. |
| 1 | 15 lb. | 79 deg. | 0.161 lb. |
| 0 | 15 lb. | 78 deg. | 0.171 lb. |
| 00 | 15 lb. | 77 deg. | 0.182 lb. |
| 000 | 15 lb. | 75 deg. | 0.186 lb. |
| 0000 | 15 lb. | 74 deg. | 0.196 lb. |
| 250000 | 15 lb. | 72 deg. | 0.190 lb. |
| 300000 | 15 lb. | 71 deg. | 0.177 lb. |
| 400000 | 15 lb. | 68 deg. | 0.158 lb. |
| 500000 | 15 lb. | 66 deg. | 0.125 lb. |

**140. The type of line construction should be decided upon** after the location of the line has been determined. The choice lies between wooden poles, steel poles, concrete poles, rigid steel towers, and the flexible tower system.

When selecting the type of line, the locality through which the line passes, the initial cost, the reliability, the ultimate life, and the maintenance should all be carefully considered.

**141. The poles or towers should be staked out** by the surveying party; following should come a digging party provided with a steel or wooden template by which the corner holes may be located. This party should be followed by another to install the concrete foundations, if such are to be used, and then by the erecting gang.

* Bibliography 3. † Bibliography 43.

## POLES

**142. Wooden poles**, though apparently the cheapest form of construction, should seldom be used, except on short or relatively unimportant lines. The life of untreated poles (Par. **143**) ranges from 6 to 15 years, depending on the type of wood and the climatic conditions. When treated, their life may reach 20 years or more. Though wooden poles and cross arms give better insulation (per pole) to the system, they may be charred or badly burned by leakage currents or by conductors that fall from insulators. Although less likely to be struck by lightning, they are usually shattered or badly damaged when struck. The large number of poles required per unit length of line, decreases the (total) insulation of the system and increases the number of insulator troubles in direct proportion.

Wooden poles are still used to a considerable extent in transmission. Sixty per cent. of the wooden poles used in the United States are cedar and 20 per cent. are chestnut. On the western coast, redwood is used to a great extent; other woods, such as pine, cypress, juniper, Douglass fir, tamarack, and oak are occasionally used. Cedar, owing to its lightness and to its long life, which varies from 10 to 30 years depending on the climate and soil, is the most common pole timber, although the supply in the eastern states is practically exhausted. Chestnut, though heavy and not as long-lived as cedar, is used in the eastern and middle states. Redwood poles have a long life, and are usually sawed from large trees. Pine, though heavy in resinous products, rots very rapidly and does not last more than 4 or 5 years unless treated. Cypress stands very well in its native climate, but is short lived in the north. The other woods are used only occasionally though the present methods of pole treatment will widely increase the timber available for poles.

**143. Average life of untreated poles.**

| | | | |
|---|---|---|---|
| Cedar | 15 years | Juniper | 8.5 years |
| Chestnut | 12 years | Pine | 6.5 years |
| Cypress | 9 years | | |

**144. Preservative treatment of poles** is attracting much attention among large users, as the available supply of timber is constantly decreasing and the price rising. Two preservatives are in general use: creosote and zinc chloride, though copper sulphate has also been used to some extent. Creosote, though expensive, is the most satisfactory preservative, as it does not contain water nor is it affected by water, and has valuable antiseptic properties. Zinc chloride is far cheaper, but as it is carried into the wood poles in a water solution, the water must be dried out again, and the pole will readily absorb moisture later.

**145. Brush treatment of seasoned poles** consists of two applications of hot creosote (220 deg. fahr.) about 24 hr. apart. The treatment should extend at least 2 ft. above the ground line, and the pole should be very dry at the time of application. This is the simplest form of treatment; it costs from 15 to 40 cents per pole, and increases the life 2 to 3 years.

**146. In the open tank method of pole treatment** the dry pole butts are placed in tanks containing hot creosote at 220 deg. fahr. (105 deg. cent.), for from 4 to 8 hr., and are then allowed to stand in a "cold" bath between 100 and 150 deg. fahr. (38 and 66 deg. cent.) from 2 to 4 hr. Where the top of the pole is subject to rot, as in the south, the whole pole may be treated by this process. The penetration is about three times as great as with the brush treatment, and the cost per pole ranges from $0.75 to $1.25, depending on the absorbent properties of the wood. The estimated increase of life is 20 to 25 years. (See Par. **230.**)

**147. In the full-cell (Bethel) process of pole treatment,** the poles are placed in an iron cylinder, about 125 ft. long and 8 or 9 ft. in diameter. Live steam at 20 lb. pressure is admitted and maintained for several hours. The steam is then blown out of the cylinder, and pumps exhaust as much of the air as possible. At the end of the vacuum period, the preservative at about 150 deg. fahr. (66 deg. cent.) is admitted and is forced into the wood under pressure. This insures a deep penetration of the preservative and a long life to the pole. No data as to the life of such poles are available, but poles in England under similar treatment are still in service at the end of 60 years. The cost is estimated at $1.10 for a 25-ft. pine pole and $2.45 for a 35-ft. pole, depending upon the amount of liquid absorbed.

Digitized by Google

**148. The burnettized creosoted butt process of pole preservation** is similar to the full-cell method, except that zinc chloride is always used in the tank. The butt, to a foot or two above the ground line, is then impregnated to a slight depth with creosote under pressure. This prevents the zinc chloride from leeching out, and is much cheaper than a complete treatment of creosote.

**149. Tabulation of pole cost, per-annum pole cost, and cost of butt treatment—western red cedar***

**150. Char and tar the butts of poles before setting** if they are not creosoted. This is done by placing the pole upon a skid over a slow fire, gradually revolving it until the butt to about 1 ft. above ground level is thoroughly charred. While hot it is given two or three coats of tar with a stiff brush and is then set. This will increase its life perhaps a year.

**151. Wooden pole specifications.** Each pole should be of good quality of live growing timber free from knots and shakes, and sound in all respects; the grain should be close and hard with the annular rings closely pitched and with a sound heart. Each pole should be straight and well proportioned, free from all objectionable bends; should have the natural butt of the tree and should be squarely sawn, without trimming. Poles should vary in size by lengths of about 5 ft.; they should be cut between the first of November and the first of March, and after being felled they should be carefully trimmed, the bark removed and the butt squared. The poles should be piled with open spaces between, raised from the ground and allowed to season for at least a year or more. After seasoning, the top of each pole should be roofed and the suitable number of gains cut for the cross arms. The specifications vary with the kind of wood.

**152. §Depth of wooden poles in the ground**

| Length over all (ft.) | Depth for straight line (ft.) | Depth curves, corners and points of extra strain (ft.) | Length over all (ft.) | Depth for straight line (ft.) | Depth, curves, corners and points of extra strain (ft.) |

**153. Wooden-pole settings.** All holes should be dug large enough to admit the pole without forcing, and should have the same diameter at the top as at the bottom. The pole may be "piked" into position, but it is usually much cheaper to employ a gin wagon, and to use the team for raising the pole. Forty to fifty poles per day can be thus raised, with only two linemen and a teamster. Poles should be set to stand perpendicular when the line is completed, but at terminals and curves the pole can be slightly inclined against the pull. When the pole is in position, only one shovel should be used in filling the hole, while three tampers pack the earth. The earth should be piled about a foot higher than the ground level.

**154. Crib-bracing** can be used, where the poles are set in loose, or marshy soils. For further discussion see Sec. 12, Par. **173**.

**155. The sand barrel** is a useful expedient in digging holes or setting poles in sandy or loose soils. See Sec. 12, Par. **173**.

**156. A concrete foundation may be used for wooden poles** where exceptional stability is desired. This concrete filling should extend at least a foot from the pole on all sides, should be carried above the ground line and bevelled to shed water, and should consist of one part Portland cement, three parts sand, and six parts broken stone or clean gravel, mixed wet. (See Fig. 47, Sec. 12.)

**157. Special pole settings.** In marshy ground, more elaborate devices, as shown in Fig. 47, Sec. 12, are often required for a satisfactory foundation.

**158. Pole repairs.** Wooden poles usually fail by decay at the ground line. If they are long enough, they may be sawed off and set again. A very satisfactory way of repairing such poles without disturbing them is to drive U-shaped rods in the poles at the ground line, as shown in Fig. 55, and fill the space with concrete. Poles reinforced in this way are said to be stronger than when new, and their life is greatly prolonged.

FIG. 55.—Pole repairing at ground line.

**159. Steel poles** cost but little more than wooden poles, when the erection and labor costs are considered, require no assembling at the point of erection, are not injured by fire, birds and insects, and are not damaged by lightning. Their field is the moderate line, with spans from 250 to 350 ft. in length running along roadways, or where space is limited. Their life is from 25 to 50 years, depending upon their upkeep.

For heavier circuits, they lack the necessary horizontal and torsional strength. The more common types are the tubular, made in sections, the diamond, the latticed-girder type, and the patented types, of which the tripartite is an example. Of these, the low weight efficiency of the first two and the difficulty with which the insides are protected from corrosion make them doubtful for high voltage transmission. The last two are extensively used. Steel poles have reached a much higher state of development abroad than in the United States.

**160. The tripartite steel pole,** shown in Fig. 78, consists of three continuous U parts, the dimensions of which are given in Par. **234**. These are held together by "spreaders" and "collars" bolted together. The strength and rigidity of the pole can be increased by increasing the number of these members, and the pole is everywhere accessible, so that it can be readily painted and inspected. Tripartite poles may be shipped either assembled or "knocked down." They can be assembled by unskilled labor. In ordinary soil, and with a concrete foundation, it has been asserted that the poles need only be buried for one-tenth their length.

**161. Steel poles should invariably have a concrete foundation,** in order to obtain adequate bearing area. Steel-pole foundations are shown in Fig. 56.

**162. Concrete poles** are coming to be used for high-voltage transmission. Their first cost and maintenance are very low, they are not injured by the attacks of insects, fire, etc., and, apparently, are not damaged by lightning. They can be used in the most accessible places only, as they must be con-

Digitized by Google

structed, in most cases when erected. Their weight results in high transportation costs. Though there are as yet no data regarding their life, it is probably considerable. Two poles, 150 ft. (45.8 m.) high, 11 in. (28.0 cm.) square at the top, 31 in. (78.7 cm.) square at the bottom, and capable of withstanding, without guys, a 2,000-lb. horizontal pull at the top, have been successfully installed by the Hamilton Power, Light and Traction Co., at the Welland Canal Crossing.

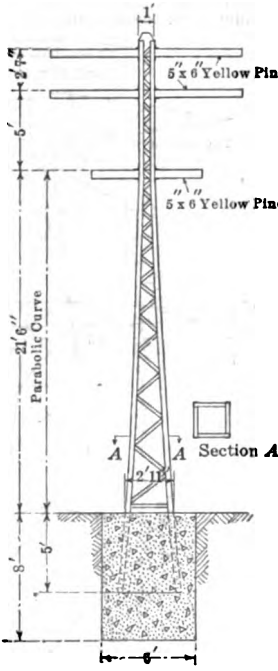

FIG. 56.—Typical steel pole.

## STEEL TOWERS

**163. Advantages.** Steel towers in the open country, and for trunk lines of large capacity and long spans, are unquestionably the best type of construction. The two systems, the rigid and flexible, are both in general use, and the latter is becoming more used. The flexible system compares favorably even with wooden poles, as far as first cost is concerned, since most of the work on it can be done by unskilled labor. The flexible towers as a rule come all assembled.

Towers are the strongest of all supports for their weight, not only under direct horisontal pull, but under torsion as well. They are free from injury by fire, attacks of insects, birds, etc., and are not wrecked by lightning. They have a life of from 25 to 50 years and possibly longer, when properly maintained.

**164. The design of a steel tower is largely the work of the structural engineer,** but the electrical engineer should be able to specify the various stresses that the tower must withstand, the height, length of cross arm, etc., and be able to check the design by calculating the stresses in the various members. Towers made with members which are too light, deteriorate very rapidly when corrosion once begins, and the cost of painting such towers, should this form of protection be found necessary, will be high. Members should never be much less than 3/16 in. (0.48 cm.) thick. Fig. 57 shows a standard tower, Ontario Hydroelectric Commission, and Fig. 58 shows a flexible tower.

**165. Protection against corrosion is obtained by painting, galvanising and sherardizing.** For proper protection, paint must be applied every 2 or 3 years, and if the tower consists of a large number of small members, the expense of painting may be prohibitive. Where the structures consist of a few members, painting may be economically used. One coat of hot dip galvanising well applied offers protection, for perhaps 30 years, except at the ground line. A shell of concrete at the ground line may increase the life of the tower materially. Sherardising or "dry galvanising," gives a uniform coating at a low cost, and offers a high resistance to wear and abrasion. If the zinc is removed by abrasion or bending, the zinc-iron alloy still offers protection.

**166. Erection of the tower** is ordinarily by gin poles or by shear poles. The former device consists of a wooden mast or a frame which must be set outside the tower base. The butt must be firmly anchored, and the pole strongly guyed, especially in the direction of the back line.

The shear pole supports the raising line and affords a means of raising

Digitized by Google

the tower by a straight away pull. The straight shear pole has a groove at the top, over which the raising line passes. The shear pole may be lowered to the ground when the raising line clears the top.

Heavy towers must often be braced at the base by some form of strut, to reinforce the tower against the stresses due to erection.

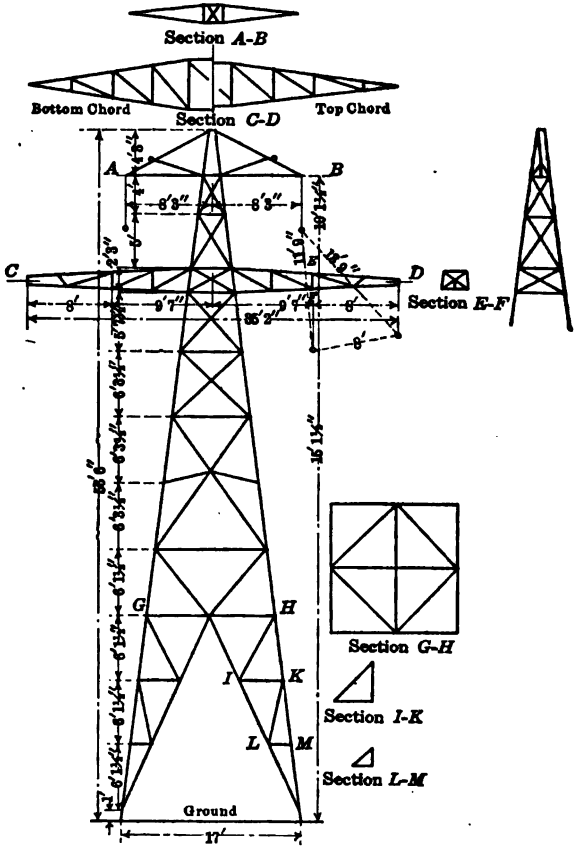

Fig. 57.—Rigid steel tower.

**167. Special structures** are often required for transpositions, and at points where the line crosses a river, a bay, or a railroad. They are also used where the line makes a sharp angle; where the line is dead-ended; and to allow the installation of line switches, protective apparatus, or outdoor substations or switching stations. Special structures are usually very expensive as compared with the standard towers, and where one of the latter will answer the purpose, it should be used.

Digitized by Google

**168. Steel towers may be set directly in the ground,** in which case, the steel should be well protected by galvanising. The footings are usually made by bolting an angle or channel iron directly to the bases of the anchor stubs. For the heavier structures, a built-up grillage is necessary. Fig. 59 shows a concrete anchor.

## POLE ACCESSORIES

**169. Wooden cross arms** may be of either Norway or yellow pine, long-leaf yellow pine, Washington fir, though other woods such as cypress, oak, spruce and cedar are used to a limited extent. Long-leaf yellow pine, and Washington fir are the best woods for high-class construction, the average life untreated being 8 and 11 years. Wooden cross arms are being used in connection with steel or concrete poles. In certain localities, cross arms are being treated to prevent decay. The full-cell treatment (see Par. 147) is usually employed, although the initial treatment by live steam is found unnecessary if the arms have been well seasoned. Cross arms should be seasoned for at least 3 months and painted with two coats of white lead paint, unless properly treated with a suitable preservative. For the voltages employed in transmission work, there has been no standard size of cross arm adopted. In the

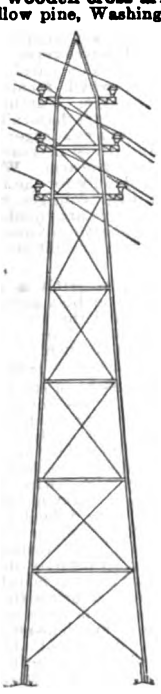

Fig. 58.—Flexible tower.

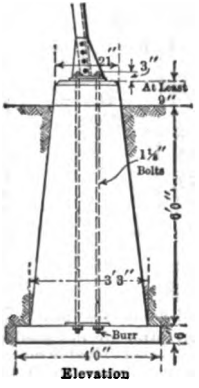

Fig. 59.—Concrete anchor for steel tower.

lighter construction, the standard electric light cross arm, 3¼ in.×4¼ in. (8.25 cm.×10.8 cm.) often answers the purpose. For heavier work, sizes ranging from 4 in.×5 in. (10.2 cm.×12.7 cm.) to 5 in. × 7 in. (12.7 cm.× 17.8 cm.) are used.

Cross arms should be snugly fitted into a 0.75-in. (1.9 cm.) gain. Unless the pole previous to erection has been treated by some preserving process, the gain should be given a good coat of mineral paint. Cross arms may be secured to the pole by two lag bolts, though in the best construction the cross arm is supported with a through bolt and braces. The cross arms on alternate poles should face in opposite directions.

**170. Cross-arm braces** are discussed in Sec. 12, Par. 179.

**171. Double cross arms** should be used where excessive stresses may occur such as at line terminals, corners, curves, and where extra precautions

Digitized by Google

against life or property hasard are required, as at railroad, highway, or low-voltage line crossings. See Sec. 12, Par. 178.

**172. The wish-bone and bo-arrow cross arms,** made of angle iron, are used for wooden-pole, single-circuit construction. The ground wire is carried on the bayonet, at the tip of the pole. See Fig. 60.

**173. Insulator pins** are made of wood, of steel and of steel in combination with porcelain. Although the wooden pin adds to the insulation, the dielectric stress in the insulator is so localized, especially in wet weather, that little is gained; wood deteriorates rapidly, being carbonized by leakage currents, and eaten by nitric acid which forms in the presence of high voltages. Furthermore, a wooden pin is weaker mechanically than a steel pin, hence requires a larger hole in the cross arm, and thus decreases the mechanical strength of the arm. **Wooden pins** should be used only for the lightest construction, and with voltages not exceeding 20,000. They are made from locust, oak, maple, hickory and eucalyptus, and should have a fine straight grain, free from knots.

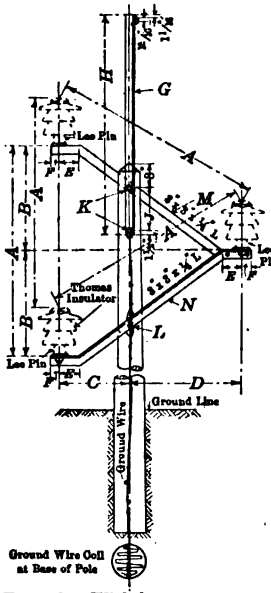

FIG. 60.—Wish-bone cross arm.

**174. A wooden pin with a centre bolt** is common. The bolt serves as a cross-arm fastening and the wooden portion holds the insulator. The advantage of this over a straight wooden pin is that a much smaller cross-arm hole is required.

**175. Steel pins** may be of steel, malleable iron, cast iron, cast steel, or combinations of these. They are much stronger than wood pins, and when well galvanized have a much longer life. They are either cemented directly into the insulator, with Portland cement, or capped with either a wooden or a lead thimble, which is screwed into the porcelain. The difficulty of replacing such insulators has been obviated by providing a steel thimble, threaded inside, which is cemented directly into the insulator, and to which the metal pin is screwed. A steel pin designed with a large shoulder which rests on the cross arm, decreases the size of cross-arm hole necessary.

**176. Clamp pins** are designed to eliminate the weakening of the cross arm due to removal of valuable material when holes are drilled for the insulator pins. Furthermore, they reduce the concentration of leakage current, and hence the burning and charring of the wood.

**177. Insulator pins with a porcelain base** (lead or wood thimble) prevent an arc from striking from the conductor to the pin, have a long life, and are mechanically strong. Even though the porcelain cracks, the pin will only bend and the insulator will not fall.

**178. Method of hanging suspension insulators.** When suspension insulators are used, the breaking of a conductor pulls the string into a nearly horizontal position. The tower connection at top of suspension string should be made as snug as possible to the under side of the cross arm, to avoid torsion on the arm.

**179. A tie wire or a clamp** may be used to fasten the conductor to the insulator. The main function of a tie is to hold the conductor securely to the insulator, and prevent it from creeping from one span to the next. Its form depends largely on the type of insulator used. Aluminum tie wires should be used with aluminum conductors, as contact with other

Digitized by Google

metals may form a galvanic couple and produce corrosion. Furthermore, a harder metal will injure the soft aluminum. A large bearing area must be allowed where aluminum is used, as it is softer than iron or copper

No. 2, No. 3 and No. 4 A.W.G. have been found most satisfactory for aluminum ties. A few typical insulator ties are shown in Fig. 61, and Fig. 62 shows two Clarke insulator clamps.

Digitized by Google

**180. Cable clamps for suspension insulators** may be designed either to allow the cable to slip through and equalize the horizontal stresses in adjacent spans, or to hold the cable to approximately breaking loads, in case of a broken span. The clamp should be designed with a liberal cable seat and long, free, well-rounded approaches, so that the conductor will not be permanently injured if a span breaks, and the string is thus thrown temporarily into use as a strain insulator.

**181. Suspension strain or anchorage clamps** should admit the wire from the span without producing any kinks, or sharp bends, and should have a long, liberal bearing surface. The cable should not be held by such devices as U or J bolts, but rather by flat smooth surfaces.

## POLE BRACES, GUYS, AND ANCHORS

**182. Pole braces** consist of shorter and lighter poles bolted against the main pole. They are sometimes preferable to guying, especially where a narrow right of way does not allow a guy wire to be used. The brace can be designed to take tension and compression; assist the main pole to resist the stresses in the direction of the line, and is not easily damaged maliciously. Owing to the increasing cost of poles, the cost of erection, and the liability of destruction by grass fires, guys are ordinarily to be preferred. Fig. 63 shows standard methods of bracing. The bearing area of

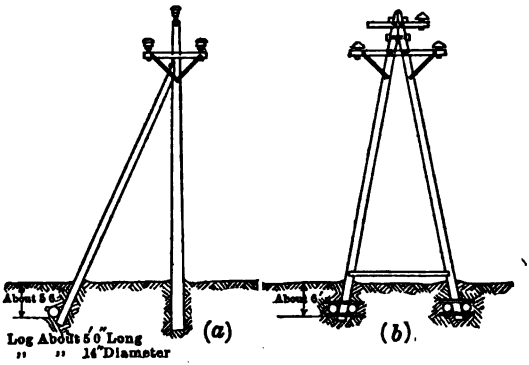

FIG. 63.—Pole brace. A-frame.

the soil can be increased by fastening planks to the base, or by placing a flat rock under the butt. A log bolted to the butt also permits the brace to take tension. An A frame, or double-pole shown in Fig. 63b may be substituted for the braced pole.

**183. Guys** are necessary to assist the supporting structure in resisting such unbalanced stresses as are produced at angles, terminals or on sloping ground. They are also used to give the line increased stability in places where a failure is very undesirable, where a hasard to life or property must be avoided, as at a railroad crossing, or where a line runs parallel to or crosses a highway. Steel towers are seldom guyed, their resistance to overturning being sufficiently large (also see Sec. 12, Par. 174, 175, 176).

Well-galvanized steel strand, a table concerning which is given in Sec. 4, should be used for guys.

**184. Straight-line guying** is used to give increased stability to the line. Approximately every twentieth pole should be guyed, in the direction of the line, either by head or anchor guys, and, if possible should be side guyed as well. Head guys should be used when a line runs over abruptly sloping ground, in order to give the line increased longitudinal stability.

Digitized by Google

**185. Guy anchors** are necessary where there are no trees, poles, or rocks to which the guy line may be conveniently attached. The simplest and most reliable form of anchor is the so-called "dead man" which consists of a log, 8 to 15 in. (20 to 38 cm.) diameter and 5 to 12 ft. (1.5 to 3.7 m.) long. A guy rod is passed through and held by a nut and washer. The log is buried to a depth of from 4 to 7 ft. (1.2 to 2.1 m.), depending on the load it must carry, and the character of the soil. Malleable iron plates may serve the same purpose.

**186. Patent anchors.** The many types of patent anchors depend for their holding power upon projections that are brought into play upon reversal of stress. The anchors are placed into position by being driven, screwed, or buried in the ground.

**187. Rock anchors** are often desirable where ledges or large boulders are encountered. They are made by setting an eye-bolt into the rock with or without cement, depending upon the character of the rock.

## CONDUCTOR CONSTRUCTION

**188. Wire stringing** may be accomplished either by securing the end of the wire and carrying the reel forward, or by maintaining the reel stationary and carrying the end of the wire forward. The former method is best adapted to light construction and long lengths, whereas the fixed reel is best adapted to heavier and shorter lengths. The conductors are drawn up by means of a team, and when the proper sag and tension are obtained, the wires are attached to the cross arms by snub-grips, thus making temporary dead-ends which remain until the lineman can attach the clamps or make the tie. Where flexible or light structures are used, these must be guyed temporarily until a permanent line anchorage is made.

**189. Phase wires may be arranged** (Fig. 64) (a) in a horizontal plane; (b) in a vertical plane; (c) at the vertices of an equilateral triangle; (d) at the corners of a square (quarter-phase); and (e) at the corners of an isosceles triangle. Only in (c) are the conductors symmetrical with respect to one another. In the other cases except (d) the inductive drop and charging current are unbalanced, but these effects are so slight that they can be neglected. The arrangement of circuits on a pole will be determined by mechanical considerations and the type of construction employed. When making inductance and capacity calculations, the *average distance* between wires, or the cube root of the product of all three of the actual distances may be used. Either method introduces only a slight error. For spacing and clearances see Fig. 54.

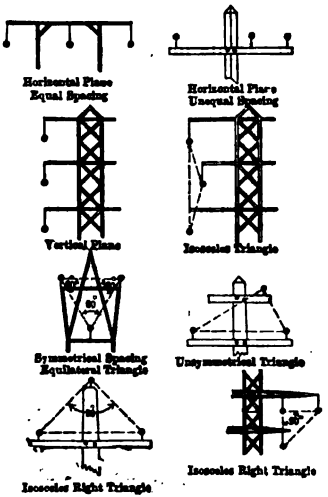

FIG. 64.—Grouping of phase wires.

**190. Cable splicing.** The insulation should be carefully removed from the ends of the cable to be spliced, close attention being given to getting the copper perfectly clean. A copper sleeve of the proper size may be used to make the joint. The joint should be left smooth and free from any little points of solder or sharp edges, as these factors tend to produce abnormal dielectric stress.

All burned or imperfect material in the insulation should be removed. The braid and tapes should be taken back far enough to allow the splices to be

Digitized by Google

completed without touching them; this is very necessary owing to their low insulating properties.

The insulation should be beveled down to a very thin edge until it has the appearance of a well-sharpened lead pencil; this bevel or taper should be very gradual. If the taper is too short, it will be difficult to put the splicing compound on with sufficient density where the insulation stops at the joint, or at the end of the scarf. More high-tension joints break down at this point than at any other one place. The remedy is a very long gradual taper or scarf.

When possible, a good rubber cement should be used, smearing the taper as far up on the insulation as the splicing compound is to go, keeping it off the copper. The cement should be allowed to dry out until all moisture has disappeared, leaving it firm and sticky. Enough pure rubber should be put on to cover the copper, running about one-third of the way up on the taper. This should be covered with a good rubber splicing compound until it is somewhat larger than the rest of the cable. Care should be taken to put as much tension on the splicing compound as it will stand in order to get it on tight, to exclude all air and make the whole a solid, dense mass. In the case of submarine cables, the vulcanizing of all patches and splices is recommended.

On small stranded joints which must be kept flexible and which cannot be soldered, a layer of tin-foil over the joint is recommended; this should be laid on before the rubber is applied, and will prevent any corrosive action of the sulphur in the rubber on the unsoldered joint. (Also see Sec. 12, Par. 219.)

**191. Joints in transmission lines** are seldom made up from the conductor itself but are almost entirely patented devices. Aluminum is not readily soldered and hard-drawn copper becomes annealed when soldered. The Western Union joint is used only for small wires. The so-called dovetail splice is made by fitting the strands of one cable between those of the other and wrapping one strand at a time tightly around the others and around the cable.

Patented joints that are satisfactory for inside wiring or short spans may give trouble when subject to the stresses incidental to the long spans employed in transmission work, unless installed with considerable care. The parallel-groove clamp is used where a jumper connection or station connection is to be made.

**192. The McIntyre joint** is used chiefly on small sizes of cable, although it has been used on sizes as large as 650,000 C.M. It is made of seamless copper or aluminum tubing, oval in section, into which each conductor is pushed from opposite ends, until the conductors project about 2 in. beyond the ends of the sleeve. The tube is then twisted three or four complete turns by special tools. This joint is efficient both electrically and mechanically.

**193. Ground-wire construction.** See Par. 80, 87. Ground wires are designed primarily to protect the line from lightning disturbances, hence should be placed well above the line conductors. With wooden poles, the so-called "bayonet" shown in Fig. 60 is commonly used. This may be a piece of angle iron or a pipe properly drilled and fitted to be fastened to the pole top to receive the ground wire. Where steel towers or poles, and consequently long spans, are used, the ground wire is often depended upon to take up some of the unbalanced stress due to the breakage of a line conductor. This is especially true when flexible towers with pin insulators are used. A ground wire is absolutely necessary to hold these towers in the correct longitudinal position, if suspension insulators are used. The ground wire should be held securely to the pole top by a clamp which is slightly flexible, has a grip of several inches, and flaring, well-rounded approaches. The use of J bolts or U bolts should not be allowed, as they will crush and weaken the cable at a point where mechanical strength is most necessary. Taps to ground connections for the same reason should not be soldered, but rather fastened by well-designed clamps. Some companies mount the ground wire on insulators as an extra conductor during the winter. The wire should be grounded at every steel pole or tower by contact with the metal work. If the metal work is completely imbedded in concrete at the base the ground should be made by driving an iron pipe, about 6 ft. (2 m.) long and 1 in. (2.5 cm.) diameter, into the ground, and

Digitized by Google

connecting it to the metal work with a copper wire.* If the soil is dry, the ground can be made more permanent by pouring salt water around the pipe. When wooden poles are used, the ground connection should be made at every pole, by running a copper wire down the pole and grounding to a pipe driven in the ground, or by coiling the wire (bare) in a flat helix and placing it under the pole-butt.

**194. Transpositions**† are made to eliminate electrostatic and electromagnetic unbalancing of the various phases; to eliminate mutual induction between parallel lines; and to prevent disturbances in neighboring telephone and telegraph circuits. The distance between power-line transpositions is a matter of judgment, and may vary from 10 to 40 miles. Many engineers question the value of transpositions, and lines are operating satisfactorily without them. Fig. 65 shows the transposition of a section of three-phase line and a telephone circuit.

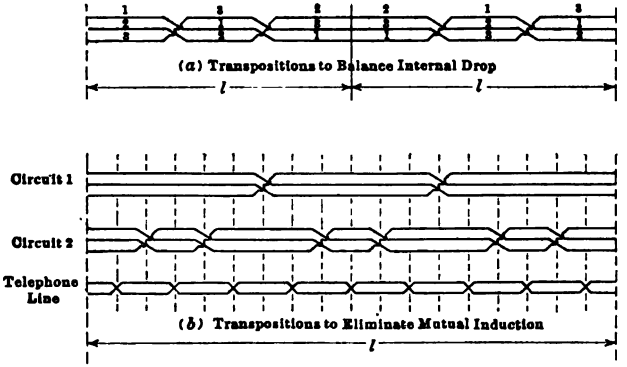

FIG. 65.—Transpositions.

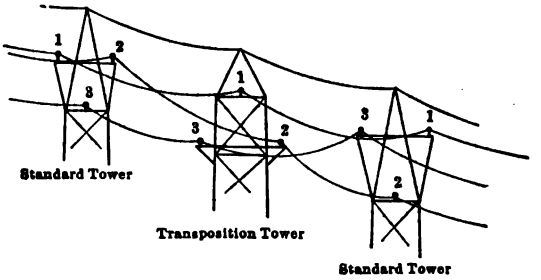
**195. Transpositions are commonly made** by rotating the delta; by gradually changing the relative positions of the wires; by dead-ends and jumpers, similar to the method employed in telephone work. The first method requires special structures that are usually interspersed between the standard towers. When the wires are arranged at the corners of a triangle, the delta is rotated through 60 deg. in one span, and through the other 60 deg. in the next span. This is shown in Fig. 66 (*a*). When the wires all lie in the same plane, resort to an intermediate triangular arrangement must be made, as shown in Fig. 66 (*b*). Both of the above methods require special structures, and the transposition spans are usually about one-half the length of standard spans, in order that proper clearance between conductors may be maintained. The jumper method, shown in Fig. 66 (*c*), requires only a standard strain tower, which may be slightly modified if the conductors happen to lie in a vertical plane.

**196. A telephone line** is essential to the satisfactory operation of every transmission system, as a means of communication between generating stations, substations and patrolmen. When possible, the telephone wires should be run on a separate pole line to eliminate disturbances and trouble caused by the high-tension circuit. The cost of an extra pole line is often prohibitive, so it then becomes necessary to carry these wires on the power line poles or towers. In this case they should be at least 8 ft. (2.44 m.) beneath the nearest power wire, and in as protected a position as possible, otherwise the telephone may be rendered useless when trouble occurs on the power line—a time when the telephone is most needed. Small telephone

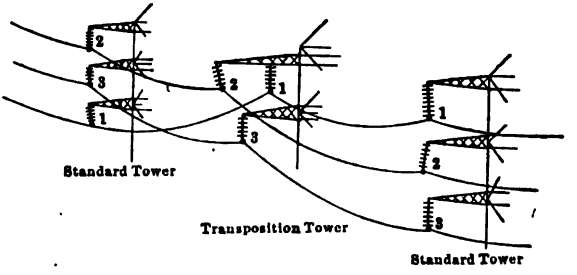
* See Bibliography 63. † Bibliography 69, 70.

Digitized by Google

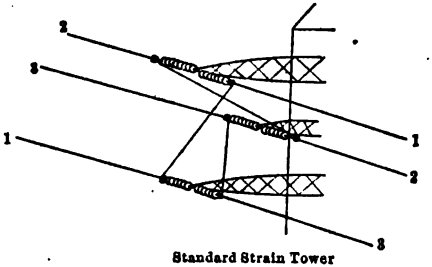
wires may be unable to withstand the stresses in occasional long spans. In this case they may be supported by a steel messenger wire, and if this latter is grounded, it helps to shield the telephone from inductive effects.



(*a*) Single Circuit Construction-Symmetrical Spacing



(*b*) Vertical Spacing

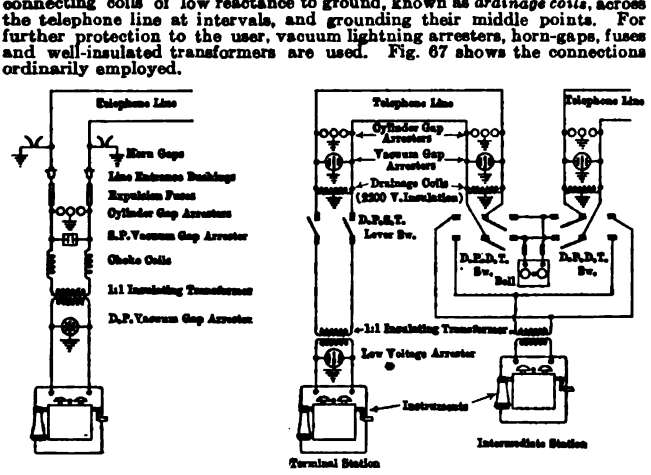


(*c*) Dead-end Jumper Method

FIG. 66.—Methods of transposition.

Digitized by Google

**197. Induced electrostatic charge** may raise the potential of the telephone circuit to a dangerous value. This potential can be greatly reduced by connecting coils of low reactance to ground, known as *drainage coils*, across the telephone line at intervals, and grounding their middle points. For further protection to the user, vacuum lightning arresters, horn-gaps, fuses and well-insulated transformers are used. Fig. 67 shows the connections ordinarily employed.



(*a*) Without Drainage Coils (*b*) With Drainage Coils

FIG. 67.—Telephone protection.

**198. Where overhead crossings are made** as over railroads or highways, extra precautions are necessary to protect life and property. In the past, a grounded cradle or basket-work beneath the lines, or some other grounding device, has been used to catch and ground the falling conductor. Patent wire clamps and hooks, out of which the conductor drops when broken, have been more or less used. Present-day practice rests on the principle that the less there is to come down, the better, and further assumes that there shall be no broken conductors. Safety is now procured by the use of short well-supported spans, having a liberal factor of safety.

**199. Extra precautions in overhead-crossing construction.*** Long spans shall be avoided; the supports at the crossing and adjacent spans shall be in a straight line; the power wires shall cross *over* the telegraph and telephone wires, whenever practicable; cradles shall in general not be used; but where the power lines run beneath the others, a cradle or bridge of adequate strength may be required; a 12-ft. (3.66 m.) side clearance to the nearest rail, a 7-ft. (2.14 m.) clearance to siding rails, and a 30-ft. (9.15 m.) headroom to the top of the rail under the most unfavorable loading conditions, is allowable practice; the clearance above the other wires shall be not less than 8 ft. (2.44 m.).

When suspension insulators are used, the crossing span shall be dead-ended, or else the maximum sag in the crossing span shall not exceed 30 ft. (9.15 m.) in case of failure in the adjacent span; the normal tension shall be allowed in the crossing and adjacent spans (see Par. 99), and no splices or taps shall occur in these spans; the pins, insulators, and attachments shall be able to hold the conductor under the greatest stress with the designated factor of safety, and the insulators shall be such that if shattered the conductors will not fall.

Wooden poles supporting the crossing span shall be side-guyed in both

*Report of the Joint Committee on Overhead Line Construction, N. E. L. A.

Digitized by Google

directions if practicable, and shall be head-guyed away from the crossing span; the next adjoining poles shall be guyed toward the crossing span.

Assumed loads shall be the resultant of dead-load, ½ in. of ice, and wind pressure of 8 lb. per sq. ft. on the ice-covered diameter at zero deg. fahr. The stresses and clearances shall be calculated for a temperature variation of from − 20 deg. fahr. to + 120 deg. fahr., except in those regions where this range is not representative. Towers or poles shall withstand a wind pressure of 13 lb. per sq. ft.

Factors of safety, or ultimate unit stress divided by allowable unit stress, shall be not less than the following:

| | |
|---|---|
| Wire and cables | 2 |
| Pins | 2 |
| Insulators, conductor attachments, guys | 3 |
| Wooden poles and cross arms | 6 |
| Structural steel | 3 |
| Reinforced concrete poles and cross arms | 4 |
| Foundations | 2 |

## HIGH-TENSION CABLES

**200. Underground and submarine cables** are often used for transmission purposes and pressures up to 60,000 volts are successfully used.

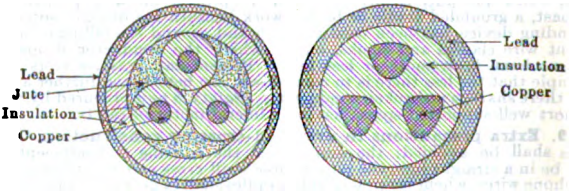
**201. Three types of insulation** are in common use, rubber compounds, varnished cambric, and impregnated paper.

(a) **Rubber compounds** consist of pure Para rubber and such mineral ingredients as sulphur, whiting, talc and litharge, which are thoroughly mixed together; the compounds are forced upon the conductors and then vulcanised.

(b) **Cambric insulation** consists of cotton cloth and a viscous filler. Each surface of the cloth is covered with multiple films of insulating varnish. The cloth is then applied to the conductor in the form of tape wound on spirally, the filler being applied between the successive layers.

(c) **Impregnated paper** insulation consists of Manila paper tapes applied spirally and evenly to the conductor, and then thoroughly impregnated with an insulating compound.

**202. Cable insulation.** In underground practice it has been found necessary to protect the insulation by a lead sheath. For submarine



(*a*) American Three-Phase Cable. (*b*) Clover Leaf Three-Phase Cable (English)

FIG. 68.—High-tension cables.

installations, cambric and paper-insulated cables have lead sheaths usually armored with steel for protection. When rubber is used, the lead sheath is unnecessary. Varnished cambric will resist water to a certain extent. Paper is worthless as an insulator if moisture is allowed to enter the cable.

Sometimes two or more of the insulations classified in Par. **201**, are used in the same cable to good advantage. For alternating-current transmission it is advisable to have all the conductors of the circuit in one cable, as the tendency to set up currents in the sheath is then practically neutralized. In all high-tension cables, the sheath should be well grounded to allow the high-voltage static charge to pass readily to earth. Where high-voltage conductors pass from the air into the cable, or from the cable into air, a large pot-head should be used, thus reducing to a minimum the high potential gradient

Digitized by Google

that would otherwise occur at this point. Fig. 68 shows sections of three-conductor high-voltage cables; (*b*) is the clover-leaf type used in Europe.

**203. Electrical disadvantages of a cable system.** A cable system differs from an overhead system in that the electrostatic capacity is much greater while the linear inductance is negligible. Hence the charging current may be equal to or even greater than the load current itself. Surges* and transient phenomena are much more common than on an overhead line of the same length.

**204. Underground cables** for high-tension work are ordinarily installed in standard ducts (see Sec. 12). All underground cables should be **lead covered.** The rubber covering may last for years after the lead sheath has been eaten away by electrolysis or has been injured mechanically.

**205. High-voltage cables† should be tested** at a potential from 2 to 2.5 times their working pressure, depending upon the system to which they are connected.

The factory test voltage $E$, which should be applied between the core and sheath of a single conductor concentric cable, having homogeneous insulation, is

$$E = Kd \log_{10} D/d \qquad (53)$$

where $D$ is the diameter over insulation, $d$ the diameter of the copper and $K$ is a constant depending on the insulating material. If $d$ is expressed in mils, $K$ is about 250 for 30 per cent. Para rubber, cambric, and paper. From this formula the proper test voltage or the proper thickness of wall for a given test voltage may be determined.

## SUBSTATIONS‡

**206. The building** is intended to shield the apparatus and equipment from the weather, as well as to furnish a shelter where repairs may be quickly made. A low-voltage station may have a fairly low initial cost. On the other hand, the large clearances required by overhead bus bars, connecting-leads, arrester equipment, etc., make the high-voltage substation a rather expensive affair.

**207. The transformers should be installed** in separate fireproof compartments which should be of such construction as to prevent burning oil from flooding the station, in case of trouble. Provision should be made for easily moving the units, so that repairs and replacements can be quickly made. Each transformer is often installed on wheels and rails, and trucks are provided in order that the large units may be readily moved.

**208. Protective equipment is often placed** indoors. The larger sizes of aluminum arresters and the large overhead clearances required for the horn-gaps often necessitate that these as well as the aluminum arresters, be placed out-of-doors. Where there are no overhead busses or inflammable material, the following clearances from the top of the horns should be allowed:§ for pressures up to 16,100 volts, 3 ft. (1 m.); from 16,101 to 37,900 volts, 4 ft. (1.2 m.); from 37,901 to 70,000 volts, 6 ft. (2 m.). At pressures above 70,000 volts, the horn-gaps should never be placed indoors. The auxiliary charging gaps for the aluminum arresters should always be in sight of the operator.

**209. Choke coils are often mounted** on post insulators on the outside of the building, especially where very high voltages are employed. For the lower voltages they may be conveniently installed on the inside wall, or directly in the switch leads.

**210. High-tension bus bars** are hung from the ceiling by suspension insulators, are suspended by ceiling insulators, or are mounted on post insulators. Owing to their low cost it is desirable to utilize suspension insulators whenever possible. Fig. 69 shows typical high-tension bus construction. (See Sec. 10, Par. 869.)

‡ See Sec. 12, Par. 51.
§ See Bibliography 64.

Digitized by Google

**211. Entrance and outlet** for lower voltages are as shown in Fig. 70. Plate glass with a central hole, slightly larger than the conductor, is often used, as it keeps the weather out. Where high-voltage must be carried into a station, great care should be used in the design and selection of suitable bushings. A simple entrance for a 110,000-volt line consists of a 5-ft. (1.5 m.) slab of glass or marble, with a small hole sufficient to admit the conductor without undue corona discharge. In Fig. 71 are shown typical wall bushings.

**The condenser type* of bushing** is built up by placing thin layers of tin foil between concentric layers of insulation, and making the areas of the foil equal, irrespective of the diameter, thus giving uniform potential distribution. Such a bushing is shown in Fig. 70 (c).

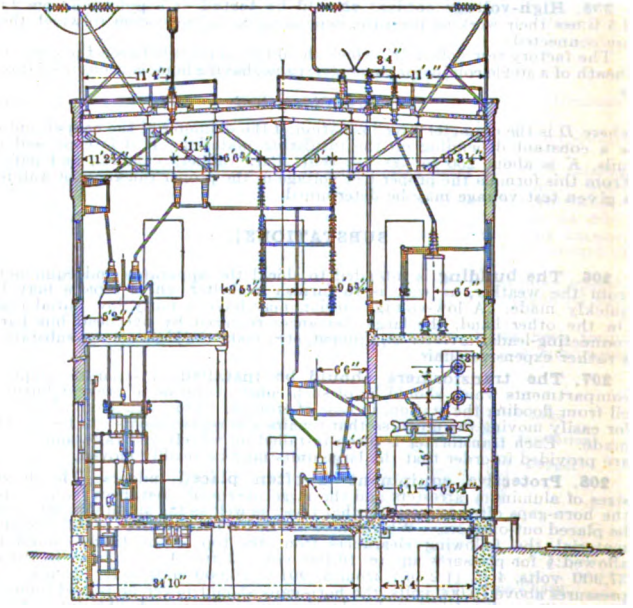

FIG. 69.—Typical substation.

**212. Roof entrances and horn-gap outlets** require a petticoated insulator in addition to a wall bushing in order to prevent trouble which might arise from rain and condensed moisture. The ratio of wet to dry flash-over should be very high. Fig. 138, Sec. 10, shows a typical roof insulator, and Fig. 72 shows standard roof construction.

**213. A Substation wiring** diagram is shown in Fig. 73, and Fig. 74 shows a typical meter panel. Meter leads A and B (Fig. 74) correspond to instrument transformer leads A and B (Fig. 73).

**214. Outdoor switching stations** are often installed at points where the amount of switching actually done does not warrant the expense of a building for housing the equipment. In such cases, a safe and economical

construction is to erect a platform on a special structure, upon which the switch-handles, transformers and other equipment are placed.

**215. Outdoor substations*** are rapidly coming into use, since the large clearance necessitated by high voltages would require a very large building. They are also used where small loads are tapped from the main line, requiring only one transformation from line to consumer. Switches, arrester equipment, power and instrument transformers have been developed to such a point that little deterioration occurs due to the weather. The outdoor equipment should be installed on paved, well-drained ground, and should be enclosed by a fence to exclude intruders. A small building may be necessary for making repairs, as well as to protect the operator and the switchboard and meter equipment. Climate, location, comparative costs of building and ground, the voltage and method of operation, are factors which largely determine the type of station. The transformers and arresters should be shielded from the hot sun and in winter the electrolytes and cooling water must be prevented from freezing. Painting the arrester tanks white tends to prevent the absorption of heat and cold. Transformer oil thickens and loses its insulating properties under extreme conditions of cold. An outdoor substation can be enlarged or modified with but little expense.

## OPERATION

**216. A chief operator should be in absolute control of the system** and should have direct telephone connection with every part of it, not only over the company's private line, but over a leased wire as well, as in times of emergency the private telephone line may be crippled. Likewise the chief operator and the substation operators should be in telephone connection with all linemen and patrolmen. In the chief operator's office there should be a dummy board showing the position of every line and switch on the system and whether each switch is opened or closed. No switch should be operated, no generator connected to or disconnected from the system, no water taken from a flume, unless the chief operator is notified and sanctions the operation. All communications should be repeated to the sender in order to prevent any misunderstandings and should be written in the log book to reduce mistakes to a minimum.

**217. A complete log** should be kept, not only by the chief operator, but by switchboard operators as well, of every transaction, loads carried, shutdowns, causes of trouble, and times of connecting or disconnecting motors and generators on the system.

* Bibliography 105, 106, 107.

Digitized by Google

A *multi recorder** for lightning and switching phenomena has been devised, whereby the exact time of switching, shut-downs and disturbances are automatically recorded.

**218. A periodic line inspection should be maintained** over all lines, the frequency of inspection depending on the country and the importance of the lines. A patrolman should be assigned to about 20 miles of line, as one man is then always within 10 miles of each section of the line. The patrolmen may cover the ground on foot, on horse-back, or with a horse and team, depending entirely upon the nature of the right of way, his duties and the distance he must travel. He should be furnished with a telephone test set and sundry tools and materials whereby he is able to make repairs, replace insulators, pins or cross arms. Some companies provide small booths every 2 or 3 miles along the line, where a small stock of insulators, pins, cross arms, wire and clamps is kept, so that material for repairs is always within a comparatively short distance. The pole switches and line sectionalising switches should be inspected at least once a month, to insure proper alignment of parts and proper operation in times of need. The patrolman should be held responsible for the proper operation of his particular section of the line.

Defective insulators which cannot be detected by inspection may be located by the use of a megger. A sound insulator should have a resistance greater than 1,000 megohms, whereas, if the porcelain or glaze is injured or cracked, the resistance will drop below 500 megohms.

**219. Line repairs and replacements** should be made only after the line is "dead." The lineman or patrolman should notify the chief operator when a particular line or section is desired. The line should then be cleared, not merely through the oil switches, but should be opened by disconnecting switches as well. Before a lineman is allowed to work the line should be well grounded, in order to eliminate the electrostatic charge. If the line closely parallels another, both ends should be grounded to eliminate any dangerous induced potential.

**220. Aluminum arresters†** should ordinarily be charged at least once a day, under normal conditions of temperature. In hot weather, or if exposed to a higher temperature, they should be charged two or three times a day. After passing a heavy discharge, and undergoing a high temperature rise, they should be charged intermittently while cooling, in order to re-form the film, which dissolves very quickly when the temperature is above normal. The charging current should be about 0.4 amp. The auxiliary or charging gap should be closed three or four times or until the arc ceases to flare. Ammeter jacks are now available for convenience in measuring the charging current. An abnormal charging current may denote trouble within the arrester, such as carbonized oil between the cones. It is desirable to charge the arresters individually, not all at the same time. (Also see Sec. 10, Par. 862.)

**221. Short circuits** may open the line when a station is provided with automatic breakers. Where non-automatic switches are used, the operator should decrease the voltage, rather than open the circuit, waiting for the line to clear. If the line does not then clear, the load should be thrown over to a spare line until repairs can be made. Where it is essential that the service shall not be interrupted, resort may be had to such expedients as operating single phase, with a ground return, etc., until the line is again in its normal condition.

## TRANSMISSION ECONOMICS

**222. Value of continuity of service.** No system should be equipped with expensive automatic control devices, duplicate lines, liberal protective equipment, and spare generating plants in order to insure continuity of service, unless the cost of an interruption or a shut-down justifies the expenditure of such capital. The line should be constructed as cheaply as is consistent with the required standard of service, without endangering life or property. Further, a system should not be extended to a distance greater than that at which there is a reasonable prospect of selling sufficient power to pay the development and operating costs of the extension.

**223. The type of line must be decided upon** after considering the reliability desired, the character of the country, transportation facilities, availability of timber, etc. Although steel construction, as an engineering

* Bibliography 58, 59.
† Bibliography 64, 65.

Digitized by Google

proposition, is far superior to wood, there are many instances where the low first cost of wood alone makes a transmission project economically feasible.

**224. The length of span should be so chosen** as to have the line cost a minimum. As the length of span increases, the number of supports and insulators decreases, but the height of the support and the conductor spacing must be increased to allow for the greater sag. The effect of these changes on cost is shown in Fig. 75 (see Bibliography 79). Under these conditions the most economical span for steel towers is about 700 ft. Other factors, such as the decreased cost for pole or tower rights on private right of way, the lesser number of insulators, with the decreased possibility of failure with the longer span, should receive due consideration.

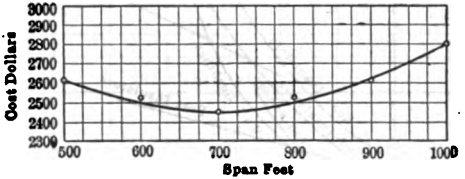

FIG. 75.—Span length and cost.

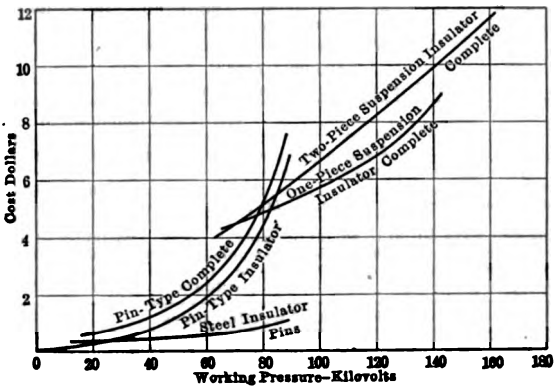

FIG. 76.—Cost of insulators.

**225. The choice of conductor material** lies between copper and aluminum, except for a few special spans. Although aluminum is about 10 per cent. cheaper than copper for the same conductance, its greater temperature coefficient of expansion and lower tensile strength demand greater sags, hence more expensive structures.

**226. The size of conductor** is influenced by mechanical considerations and by the amount of energy that it is permissible to waste in transmission. Line regulation may require a larger conductor than is economically demanded. When energy may be generated and sold at a low rate per kw-hr., a much smaller conductor is justified than if the reverse be true.

**227. The choice of voltage** is determined by the amount of power and the transmission distance. The conductor cross-section varies inversely as the square of the voltage, but the cost of insulators, supporting structures, stations, protective equipment and transformers increases as the voltage is increased. These last three items are independent of the length of the line, so would make a higher voltage on a long line economically desirable, neglect-

Digitized by Google

ing other considerations. Roughly, a thousand volts per mile seems to be the criterion adopted by engineers. An 80,000-volt line presents no greater operating difficulties than a 30,000-volt line. Surge voltages are, however, dependent upon the current and systems have been designed to operate at a higher voltage than is economically demanded, in order to secure greater freedom from surges.

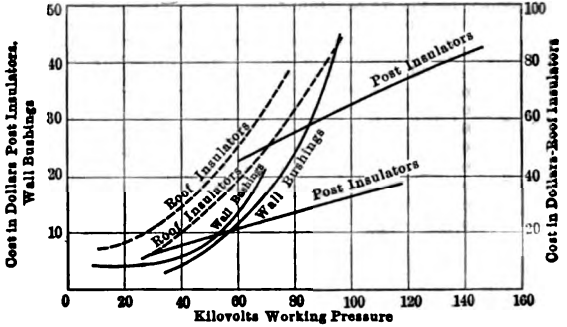

FIG. 77.—Cost of station insulators.

## COST DATA†

### 228. Preliminary and right of way*

| | Minimum cost per mile | Maximum cost per mile |
|---|---|---|
| Surveying | $5.00 | $10.00 |
| Right of way, perpetual easement, 60 poles per mile. | | |
| Along highways $0.50 to $2.00 per pole | 25.00 | 100.00 |
| Along section lines $0.50 to $5.00 per pole | 25.00 | 250.00 |
| Through fields, $2.00 to $10.00 per pole | 100.00 | 500.00 |
| Towers, 10 per mile, $9.00 to $20.00 per tower. | 90.00 | 200.00 |

### 229. Cost of wooden poles

| Length, ft. | Top diam., in. | Approx. butt diam., in. | No. per carload | *Cost Northern Cedar f.o.b., Minneapolis, per pole | *Cost Western Cedar, f.o.b., Spokane, per pole | Cost Chestnut - f.o.b., Western Mass, per pole | *Cost Cypress f.o.b., St. Louis, per pole | Cost per pole unloading, cents |
|---|---|---|---|---|---|---|---|---|
| 30 | 7 | 11 | 55–95 | $4.60 | $2.50 | $3.25 | $1.20 | 5–8 |
| 35 | 7 | 12 | 50–70 | 6.70 | 3.25 | 4.00 | 2.00 | 8–12 |

**Cost of transmission line per mile, semi-flexible steel structures.**

**Specifications:**

33,000 volts working pressure, No. 2 B. & S. copper wire
400-ft. pole spacing, one pole line
13 poles per mile
3-disc suspension type insulators
$\frac{7}{16}$-in. ground wire (standard galvanised wire)

**Material, labor, etc.**

| | | |
|---|---|---|
| 13 | Towers (steel frames) 43-ft. high with cross arms, telephone clips and pole steps, complete, f.o.b. Central Ohio @ $53.00 per tower | $ 689.00 |
| | Cartage @ 80 cents per frame | 10.40 |
| | Hauling (railway) @ $1.25 per frame | 16.25 |
| | Digging of holes @ $1.50 per frame | 19.50 |
| | Erecting of frames, @ $2.00 | 26.00 |
| | Concrete foundations for curve frames and frames in swampy ground | 40.00 |
| | Guying of poles | 30.00 |
| | Crushed stone for regular foundations | 6.00 |
| 3 | Miles No. 2 B. & S. copper wire @ $181.20 | 543.60 |
| 2 | Miles No. 10 B. & S. copper clad @ $25.00 | 50.00 |
| 1 | Mile $\frac{7}{16}$-in. S.-M. steel strand wire | 75.00 |
| 39 | Suspension insulators, porcelain 3-disc unit sets including suspension hooks and wire clamps @ $3.50 | 136.50 |
| 26 | Telephone insulators and pins @ 20 cents | 5.20 |
| | Stringing 3 miles No. 2 B. & S. @ $18.00 | 54.00 |
| | Stringing 2 miles No. 10 B. & S. @ $12.00 | 24.00 |
| | Stringing ground wire | 20.00 |
| | Miscellaneous material | 10.00 |
| | Painting of structures @ $1.60 each | 20.80 |
| | Soldering material | 5.00 |
| | Clearing and trimming of trees | 4.50 |
| | Damage, expense to property owners | 20.00 |
| | Camp expenses | 16.00 |
| | Wasted materials | 5.00 |
| | Contingencies and incidentals, 6 per cent | 109.61 |
| | Supervision and inspection, 5 per cent | 96.82 |
| | Total construction cost per mile with steel towers exclusive of right of way | $2,033.18 |
| | Right of way @ $15.00 per frame | 195.00 |
| | Total cost including right of way | $2,228.18 |

## DISTRIBUTION SYSTEMS

### CLASSIFICATION OF SYSTEMS

**1. Distributing circuits may be classified** as to the nature of the current—direct or alternating; as to method of connection—series or multiple; and further as to phase, number of conductors, voltage and frequency. The following is a statement of the field of application of the principal kinds of distributing circuits.

**2. Direct current** is best adapted to use: (a) where the distances are small, (b) where there is variable-speed machinery, and (c) where there is an area of congested load for which storage-battery reserve is necessary to insure continuous service.

**3. Alternating current** is best adapted to use where the distances are greater and the density of the load not sufficient to justify low-tension distribution without transformation from a higher voltage.

**4. The use of series systems** is limited almost entirely to street and other lighting which is all in use at the same time. These systems are inherently high-tension in character and are, therefore, not suitable for general purposes. They are operated by direct current or alternating current at a constant current of 5 amp. to 10 amp. in American practice. In Europe there are several direct-current series power transmission systems in operation utilising a series of motor generators as the converting medium (Sec. 11).

**5. Multiple or parallel systems** are used for general purposes almost exclusively. When **direct current** is used a nominal voltage of 110, 220, or 550 is employed, the last named being used only for power distribution. The Edison three-wire system at 220 and 110 volts is common in large installations.

When **alternating current** is used, the primary mains are operated at a nominal voltage of 2,200. Single-phase, two-phase, and three-phase circuits are in general use, with frequencies of 25 or 60 cycles. In general, single-phase distribution is used for lighting and small power service, and two-phase or three-phase distribution is used for larger power loads.

**6. Frequency.** Twenty-five cycles is standard where most of the energy is converted to direct current for lighting and railway service or other purposes. Sixty cycles is standard where the energy is delivered for retail consumption as alternating current. Other frequencies such as 30, 33, 40, 50 and 133 cycles are in use in some of the older installations in America and in Europe. Sixty-two and one-half cycles is used in some modern systems where the supply is derived from a 25-cycle system, this frequency giving a better design of frequency-changer apparatus.

### GENERAL APPLICATIONS

**7. The single-phase system,** requiring only the simplest form of electric circuit, has the advantage of a minimum number of conductors, and hence the minimum first cost for distributing mains. The feeders, however, require 33 per cent. more copper than equivalent three-phase feeders. Single-phase motors are more complicated and cost more than polyphase motors, and usually produce more disturbance of pressure, in starting, than three-phase machines. The distribution of energy by single-phase circuits is, therefore, usually limited to motor units of less than 10 h.p., although motors up to 35 h.p. are used in single-phase systems with good success. This system is used very generally for lighting circuits, in both single-phase and polyphase systems.

Digitized by Google

**8. Two-phase systems.** Two-phase distribution is effected by the use of two single-phase circuits in a quarter-phase relation, making a **four-wire system**; or by means of a **three-wire** system in which one conductor of each phase is common.

**The four-wire system** is substantially the same as a single-phase system, except that two-phase motors may be used. The principal advantages of two-phase systems are that there are only two phases to keep balanced and only two transformers are required to supply polyphase energy to motors.

**In a three-wire, two-phase system,** the current in the common or neutral conductor is 1.414 times the current in the outer conductors, with balanced load. When all conductors are the same size, the copper required is 75 per cent. of that needed for a four-wire system. When the neutral is 40 per cent. larger than the outer conductors, the amount of copper required is 85 per cent. of that needed for a single-phase system or a four-wire, two-phase system. In the primary mains, which are all the same size, the three-wire two-phase system is as economical of copper as the three-wire, three-phase system. The line drop in this system is such that even with balanced load the drop in the two phases is not the same, making voltage regulation difficult, unless line-drop compensators are employed. The three-wire circuit cannot be used where the mid-points of the quarter-phase generator windings are tied together, as is the case in some machines.

**9. Three-phase, three-wire system.** This system is commonly employed for general distribution, since it is readily derived from a three-phase transmission system; it is also well suited to power distribution, and requires but 75 per cent. as much copper in the feeder system as an equivalent single-phase system. The three-wire distributing mains are usually carried only where motor service is required, the lighting service being taken on single-phase branches from the three-phase main. Users of small motors, up to about 5 h.p., are generally supplied from a single phase; while the larger motors, up to 30 h.p. or 40 h.p., are supplied from two phases with the open-delta connection.

**10. Three-phase four-wire system.** In primary distribution this system is usually operated at 3,800 volts between phase wires and 2,200 volts between any phase wire and neutral. This gives the advantage of 3,800-volt distribution in the feeder system and permits the supply of energy over a radius about twice as great as with 2,200-volt systems, with the same regulation. Standard 2,200-volt transformers and other accessories are used, and the lighting branches are single-phase. The unbalanced load is carried by the neutral wire, and with the use of line-drop apparatus, good pressure regulation is possible with any proportion of unbalanced load.

The four-wire distributing mains are carried only where there are motors or large loads to be served, and but three wires are needed for installations of less than 30 to 40 h.p., which may be served by two transformers connected in open delta. The wide range permissible has led to the adoption of this system in many of the larger cities of the United States. It is also well suited to the supply of suburban districts and rural communities, where double-voltage, 4,400–7,600 volts may be used to supply a group of towns and villages, the pressure being regulated independently on each phase at the source of supply.

**11. Direct-current low-tension systems** find their principal field of application in important parts of cities where the protection of the storage battery reserve is of great value, and where there are many elevators, printing presses and other variable-speed machines, and where space for transformers would be difficult to secure in public thoroughfares. The principal limitations of direct-current distribution are the small radius of distribution, and the necessity for rotating machinery to transform the energy from an alternating-current source of supply. This requires a greater number of substations to cover a given area, and these are more expensive both in first cost and operation than alternating-current substations.

**12. Two-wire, 500-volt, direct-current systems** are operated in some cities where they were originated to supplement single-phase systems in the early period of development. The duplication of mains necessitated by a separate power-service results in an excessive investment and 500-volt systems are being eliminated wherever possible.

**13. Combination systems.** Various combinations of alternating-cur-

Digitized by Google

rent, and direct-current, or 25-cycle and 60-cycle systems, are necessary in the larger cities. The direct-current supply is usually derived through synchronous converters or motor-generators from an alternating-current generating system. The 60-cycle supply is sometimes derived from a 25-cycle system by the use of synchronous motor-generators called frequency changers. In some cases both 25-cycle and 60-cycle generating systems are maintained, and the frequency changers are used as a connecting link between the two systems.

## TYPES OF CIRCUITS

**14. Series circuits.** Two general types of arrangement are employed in laying out series circuits, the "open loop," and the "parallel loop." In the **open-loop** circuit (Fig. 1) the lamps are connected by following the shortest available route, without reference to the separation from the return conductor. This permits a minimum length of circuit, but makes it difficult to test for a break, or open circuit in the line. In alternating-current circuits it also tends to increase interference with telephone systems.

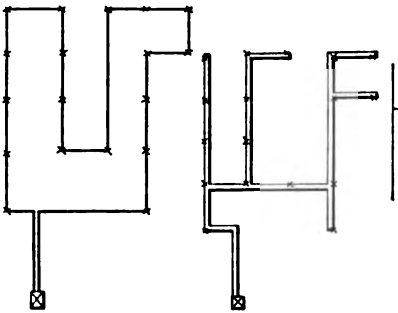

FIG. 1.—Open-loop series circuit.

FIG 2.—Parallel-loop series circuit.

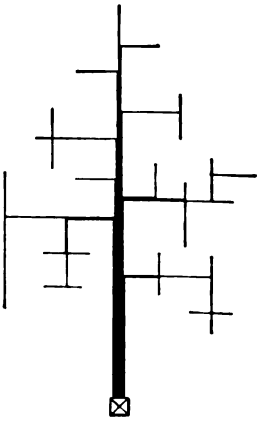

FIG. 3.—Tree-system of distribution.

The **parallel-loop** circuit (Fig. 2) is laid out in such a way as to be near the return conductor at many points. This affords frequent opportunity for test and minimises inductive disturbances, but usually requires a greater mileage of conductor than the open-loop circuit. A combination of parallel loops with small open loops may often be used to advantage.

**15. Multiple circuits.** The arrangement of multiple circuits may take any one of a number of forms as conditions require. The simplest and least expensive circuit is that commonly known as the "tree" circuit (Fig. 3); it is thus named because it is branched off in various ways, and has its heaviest branches nearest the source of supply. The tree system is not adapted to supplying a uniform distribution pressure and is only suited to short branches and those branches in which the current values are small as compared with the conductor capacity.

**16. A system of feeders and mains** is the arrangement most commonly employed in city distribution for lighting and power-service. This takes the form of a network in low-tension systems (Fig. 4), and an isolated or dead-ended main system in primary distribution (Fig. 5). In the low-tension network the system of mains is designed to be of such capacity as to carry the load units which are tapped off from house to house, and the feeders are provided in such number, of such size and at such points as will maintain an even distribution of pressure, within a few per cent., over the entire system of mains.

Digitized by Google

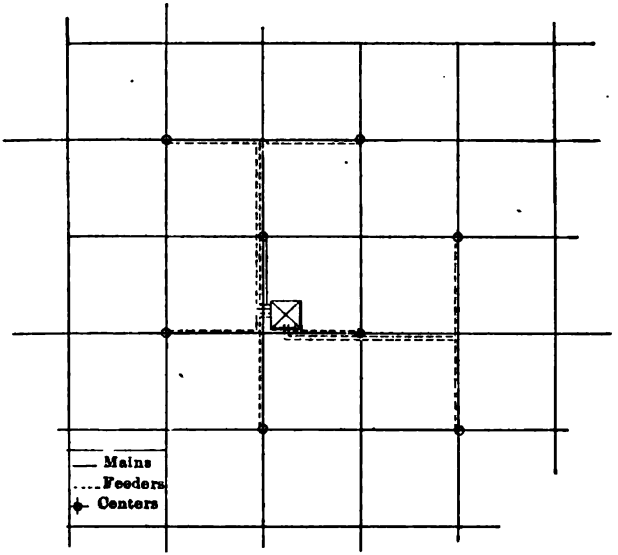

FIG. 4.—Feeders and mains in a direct-current network.

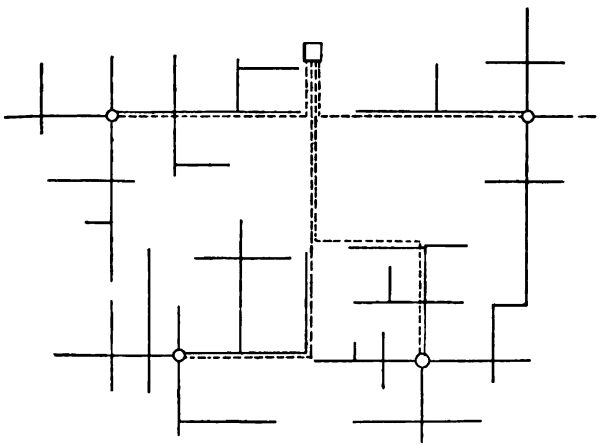

FIG. 5.—Feeders and mains in alternating-current distribution.

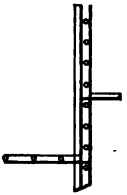
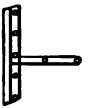
Digitized by Google

**17. Primary-main systems** are usually supplied by a feeder at a **centre of distribution**, this point being a junction from which the load is distributed in four or more directions. These mains are not interconnected, because it is not practicable to provide fuse protection, and in most cases not much is to be gained by such connection.



**18. The loop feeder** (Fig. 6), is used where the load is distributed in a long continuous line with few side branches. This arrangement distributes the pressure more evenly along the line than is possible with other types of circuit.

**19. Ring feeders.** Where it is desired to provide emergency supply to units of load in one general direction from the point of supply, the most economical means often consists of the type of feeder known as a ring circuit (Fig. 7). The capacity of the ring must be sufficient to carry the combined load of all the units, in case either of the links adjacent to the point of supply should fail.



**20. Urban transmission systems.** In cities having too large an area to permit an economical distribution of electrical energy from a single point, it becomes necessary to transmit energy from a generating station (located at a point convenient to coal and water supply) to substations centrally located with reference to the districts served. This transmission system, in the larger cities, becomes practically a bulk-supply distribution system. The same condition exists where hydroelectric energy is brought from a distance for distribution in a large city. These urban transmission systems are universally three-phase; where two-phase energy is generated, it is converted to three-phase energy for transmission.

FIG. 6.—Loop feeder.

**21. Pressures and frequencies in urban transmission.** The pressures in common use are 6,600, 9,000, 12,000, and 13,200 volts, and the standard frequencies are 25 and 60 cycles. The use of 25 cycles is preferable where the principal portion of the energy is converted to direct current for lighting and railway service, because the synchronous converter is more economical in operation and in first cost, at 25 cycles, than at 60 cycles. The use of 25-cycle energy for general lighting purposes is not satisfactory, and the transformers, motors, etc., are more expensive; hence it is necessary to convert the retail supply of alternating current to 60 cycles, to put it into form which is readily saleable.

The use of 60 cycles is desirable where the major part of the energy is to be distributed as alternating current. This permits the use of transformer substations, instead of frequency-changing motor-generators which are necessary for securing 60-cycle energy from a 25-cycle supply.

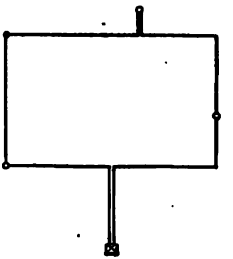


FIG. 7.—Ring feeder.

**22. Underground urban transmission.** Urban transmission lines are necessarily placed underground to a large extent. This involves the use of paper-insulated lead-sheathed cables, which are made up with the three conductors of the circuit under one sheath. With standard 3.5-in. ducts, the largest size of cable which can be drawn into the duct is about 3 in. outside diameter, and this limits the maximum size of the conductor which can be used with a given thickness of insulation. At pressures of 6,600 volts, 400,000-cir. mil sector-shaped conductors are the largest in use. At 9,000 to 13,000 volts, about 300,000 cir. mils is the

Digitized by Google

maximum size. This fixes the maximum load which can be carried continuously on such cables at from 4,500 to 6,000 kv-a.

In the larger cities where certain substations distribute loads of 8,000 to 15,000 kw., several cables are required to supply each substation, and it is desirable to have cables of the maximum size.

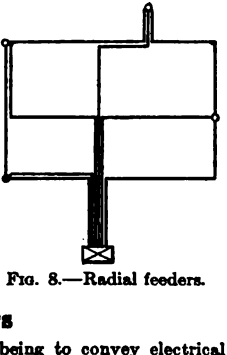

FIG. 8.—Radial feeders.

**23. Reserve cables.** A reserve cable must be provided for use in case of the failure of any of the cables which normally carry the load. This reserve may be secured by having a spare cable direct from the power-station, or by means of a **tie line** from a neighboring substation, or by the use of a ring system. When substation loads are small as compared with the cable capacity, the ring system is often found to be the most economical (Fig. 7). After the combined loads of the substations exceed the capacity of one side of the ring, additional capacity may be secured by adding **radial** feeders (Fig. 8). This is the situation in the larger cities where substation loads run from 2,000 kw. upward.

## DESIGN OF CIRCUITS

**24. General.** The function of a conductor being to convey electrical energy from the source of supply to the consuming device, it must be of such size that it will not absorb too great a percentage of the energy or become overheated. The problem of designing a circuit is, therefore, one of determining what size of conductor should be used to limit the loss of voltage to a specified amount, when distance and current-strength are known, and also determining whether the size needed for the specified voltage drop is sufficient to carry the current safely.

**25. Direct-current circuits.** In direct-current circuits the current and the resistance are the only factors affecting the drop in voltage. The resistance of a mil-foot of pure annealed copper at 68 deg. fahr. being 10.4 ohms, that of a conductor $D$ ft. long and $M$ cir. mils in area is $R = (D \times 10.4)/M$. The drop with current $I$, therefore, is

$$E = IR = \frac{I \times D \times 10.4}{M} \text{ (volts) or } M = \frac{I \times D \times 10.4}{E} \quad \text{(cir. mils)} \quad (1)$$

If both conductors are of the same size the total drop is twice the drop in one conductor, as found by Eq. 1; if they are not of the same size, the drops in the different sizes must be computed separately and added together.

**Example.** A two-wire circuit is to carry a load of 100 amp. a distance of 300 ft. with a drop of 5 volts. What size of conductor must be used?

$$M = \frac{2D \times I \times 10.4}{E} = \frac{2 \times 300 \times 100 \times 10.4}{5} = 124{,}800 \text{ cir. mils.}$$

The nearest size is No. 2/0, A.W.G., which should be used.

**26. The calculation of direct-current drop at any load** is readily determined, where the size of the conductor is already fixed, by the use of the formula, $E = 2IDR/1{,}000$, in which $R$ is the resistance per 1,000 ft. of conductor, the formula gives the total drop in the two wires of the circuit.

**Example.** A circuit of 4/0 cable, 500 ft. in length, is to carry a load of 190 amp.; what will be the line drop? The resistance of No. 4/0 conductor is 0.049 ohm per 1,000 ft. (Par. 21); $D = 500$ ft. The drop is

$$E = \frac{2 \times 190 \times 500 \times 0.049}{1{,}000} = 9.3 \text{ volts.}$$

**27. Three-wire direct-current circuits.** In making calculations for a **three-wire Edison circuit**, separate computations are made for each conductor if the load is appreciably unbalanced.

**Example.** A circuit having two No. 4/0 A. W. G. outer wires and a No. 0 **neutral**, 1,000 ft. long, carries a load of 150 amp. on the positive side and 110 amp. on the negative side; what is the drop on each side of the circuit?

Digitized by Google

The resistance of 1,000 ft. of No. 4/0 = 0.049 ohm, and that of No. 0 = 0.098 ohm, per 1,000 ft. (Par. 21).

$E = IR = 150 \times 0.049 = 7.35$ volts drop on positive wire;
$E = IR = 110 \times 0.049 = 5.4$ volts drop on negative wire;
$E = IR = 40 \times 0.098 = 3.92$ volts drop on neutral wire.

The drop in the neutral wire is added to the drop on the "heavy" side and subtracted from that on the "lighter" side, making the total drop $7.35 + 3.92 = 11.27$ volts on the "heavy" side, and $5.4 - 3.92 = 1.48$ volts on the other side.

**28. Alternating-current circuits.** In an alternating-current circuit, voltage drop is caused by the combined effect of (a) resistance, (b) inductance, and (c) capacity. **The component of drop due to resistance** is governed by the same laws which govern direct-current circuits, and is in phase with the current. **The component due to inductance** (reactance drop) is a counter e.m.f. set up by the magnetic field as it reverses with each alternation; this back e.m.f. is a quarter cycle behind the current wave, and the component of impressed e.m.f. required to overcome it is a quarter cycle ahead of the current. The resistance drop and the reactance drop may be represented, therefore, by two sides of a right triangle.

**The reactance of a circuit** is $\omega L$, where $\omega = 2\pi n$ and $n$ = frequency in cycles per second; $L$ = inductance in henrys. The inductance is a measure of the number of lines of force per ampere linked with the circuit; it increases, therefore, as the separation of the conductors of the circuit is increased, or with the introduction of iron into the magnetic field, since either of these increases the number of lines of force linked with the circuit.

**29. Table of wire resistance and reactance.** The table in Par. 31 gives the reactance drop in volts per ampere, for 1,000 ft. of conductor, for the distances of separation and sizes of wire commonly used in transmission and distribution work. It should be noted that the *reactance increases as the separation is increased.*

**30. Example of calculation of resistance and reactance drops.** A single-phase circuit 10,000 ft. long operates at 60 cycles and carries a load of 100 amp., with No. 0 wires 12 in. apart. What are the values of the inductive and the ohmic components of drop, and the impedance drop? The reactance per 1,000 ft., per amp. per wire, for No. 0 wires 12 in. apart is $X = 0.1043$. The resistance is 0.098 ohm. per 1,000 ft. The inductive component of the impedance of the circuit is

$X = 2D \times I \times 0.1043/1{,}000 = 2 \times 10{,}000 \times 100 \times 0.1043/1{,}000 = 208.6$ volts.

The ohmic component is $R = 2 \times 10{,}000 \times 100 \times 0.0981/1{,}000 = 196.2$ volts.

The impedance drop in the circuit is

$$\sqrt{(209)^2 + (196)^2} = 286 \text{ volts.}$$

The length of the line $OA$ in Fig. 9 is proportional to the resistance component, that of $AB$ represents the inductive component and $OB$ the resultant of the two. If the circuit consisted of two No. 6 wires the resistance component would be 788 volts, the inductive component 241 volts, and the impedance drop would be

$$\sqrt{(788)^2 + (241)^2} = 824 \text{ volts.}$$

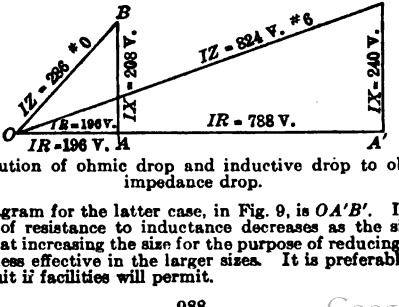

FIG. 9.—Resolution of ohmic drop and inductive drop to obtain total or impedance drop.

The e.m.f. diagram for the latter case, in Fig. 9, is $OA'B'$. It is apparent that the ratio of resistance to inductance decreases as the size of wire is increased, so that increasing the size for the purpose of reducing the pressure-drop becomes less effective in the larger sizes. It is preferable to install an additional circuit if facilities will permit.

**32. Resistance and inductance factors.** The **resistance factor** of a circuit is the ratio of its resistance to its impedance. Likewise the **inductance factor** is the ratio of the inductive reactance to the impedance. The square root of the sum of the squares of these two factors is equal to unity. The values of inductance factor which correspond to various common values of resistance (or power) factor appear in the following table:

| Resistance (or power) factor, per cent..... | 50 | 60 | 65 | 70 | 75 | 80 | 85 | 90 | 95 | 97.5 | 100 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Inductance factor, per cent..... | 86.6 | 80 | 76 | 71 | 66 | 60 | 53 | 44 | 31 | 22.2 | 0 |

**33. Single-phase line drop.** In an alternating-current circuit the pressure-drop is determined from the resistance and the inductance components in conjunction with the power-factor of the load which the circuit is carrying. The line drop is a maximum when the power-factor of the load equals the resistance factor of the line.

Referring to Fig. 10, the line *OE* represents the pressure delivered. *OR* is the component of *OE*, which is doing useful work; *ER* is the component of self-induction, or inductive component, which causes the current to be out of phase with the impressed voltage at the load. *EL* is the resistance component of the line drop, and *LP* is the inductive component. The resistance component of the line drop, *EL*, and the power component of the impressed load voltage, *OR*, are in phase with each other; and the inductive components *ER* and *LP* are in phase. The resultant *OP* is the bus pressure, or impressed line voltage, necessary to deliver a pressure *OE* at the end of the line. The net line drop is the numerical difference between *OP* and *OE*. In the case of non-inductive load, such as incandescent lamps, the inductive component *ER* disappears, and the impressed voltage at the lamps takes the position of *OF* (=*OE*). The impressed line pressure necessary to deliver *OF* at the lamps is *ON*, or the resultant of *OM* (=*OF*+*EL*) and *MN* (=*LP*), and the drop is the numerical difference between *ON* and *OF*.

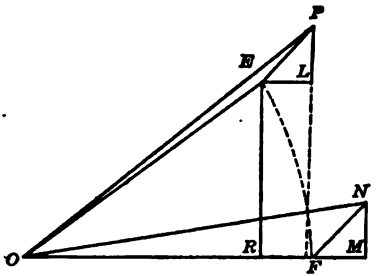

FIG. 10.—Diagram of alternating-current line-drop under inductive load.

**34. Example of calculation of single-phase line drop.** Given a load of 100 amp. of 2,200 volts, single-phase, delivered at the end of a two-wire line of No. 0 copper wire, 4,500 ft. long, with wires 12 in. apart, a frequency of 60 cycles and a power-factor of 80 per cent., what is the line drop?

The power-factor being 80 per cent., the corresponding inductance factor is 60 per cent., from the table in Par. 32. Using the notation of Fig. 10:

$$OR = 0.80 \times 2{,}200 = 1{,}760 \text{ volts.}$$
$$ER = 0.6 \times 2{,}200 = 1{,}320 \text{ volts.}$$

The line resistance drop per 1,000 ft., per ampere, for No. 0 wire (Par. 31) is 0.098 volt. Hence the total line resistance drop is

$$EL = 2 \times 0.0981 \times 4.5 \times 100 = 88 \text{ volts.}$$

The line inductive drop per 1,000 ft., per ampere, for 12-in. centres, is 0.104 volt, and therefore

$$LP = 2 \times 0.1043 \times 4.5 \times 100 = 94 \text{ volts.}$$

The total power (resistance) component is $OR+EL$, or $1{,}760+88 = 1{,}848$ volts, and the total inductive component is $ER+LP$, or $1{,}320+94 = 1{,}414$ volts. The resultant of these two is

$$OP = \sqrt{(1{,}848)^2+(1{,}414)^2} = 2{,}327 \text{ volts.}$$

This is the pressure necessary to deliver 2,200 volts at the end of the line.

Digitized by Google

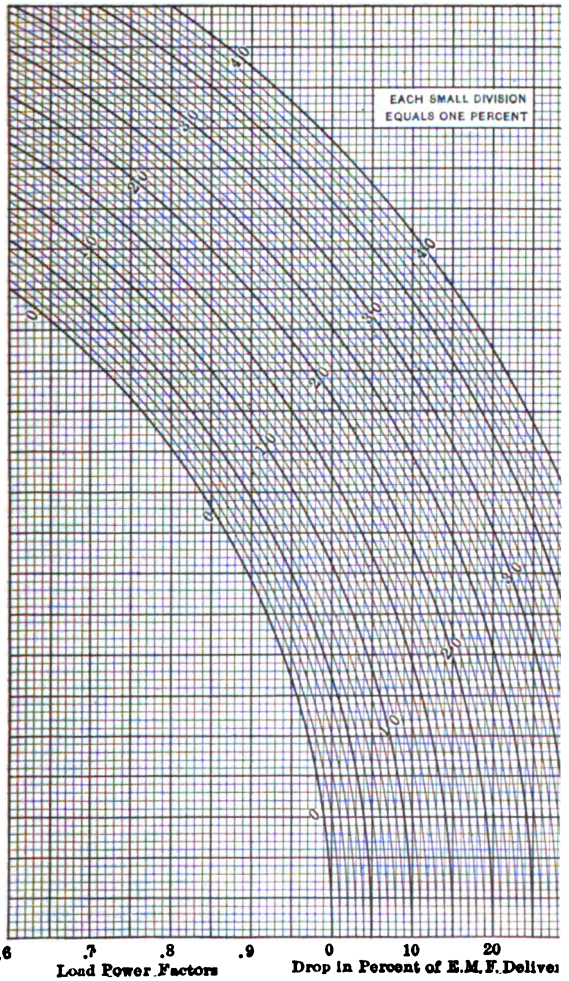

FIG. 11.—Mershon chart for calculating drop in alternating-current

Digitized by Google

The net line drop is, therefore, 127 volts or 5.8 per cent. of the receiver voltage.

If a lighting load of 100 amp. at 100 per cent. power-factor were being carried, the inductance factor $ER$ would be zero and $ON$ would be

$$\sqrt{(2{,}288)^2+(94)^2}=2{,}290 \text{ volts.}$$

At 100 per cent. power-factor, therefore, the drop is 90 volts.

**35. Mershon diagram.** R. D. Mershon has devised a diagram by means of which **line-drop calculations,** which do not involve charging-current effects, may be made with facility and yet with sufficient accuracy for all ordinary purposes. This diagram,* Fig. 11, is based on the principles of the diagram of Fig. 10. The concentric circles are described about a centre, to the left of the diagram, which corresponds to the point $O$ in Fig. 10. The divisions are made in percentages so that the scale may be applicable to any voltage. The use of the chart may be illustrated by the example of the circuit of No. 0 wire carrying a load of 100 amp. at a distance of 4,500 ft. (Par. **34**). The ohmic drop is 88 volts, or 4 per cent., while the inductive drop is 4.3 per cent. The power-factor is 0.8. The base of the 0.8 power-factor line in Fig. 11 is the point $R$ in Fig. 10. The point where the 0.8 power-factor line intersects the first circle is the point $E$ in Fig. 11. Passing from this point to the right, 4 divisions, and then upward, 4.3 divisions, a point is reached which is a little below the 6-per-cent. circle; this point is equivalent to the point $P$ in Fig. 10. The net line drop is 5.8 per cent. of 2,200 = 128 volts, compared with 127 volts by calculation.

If the load on the circuit has a power-factor of 100 per cent., one begins at the base of the 100-per-cent. power-factor line, passes to the right 4 divisions and then up 4.3 divisions. The drop is found to be about 4.1 per cent., or 90 volts, as compared with 90 volts calculated.

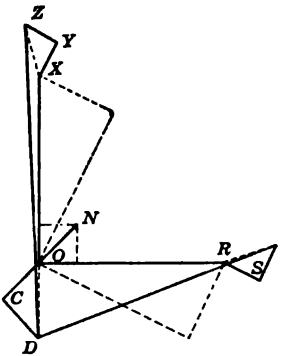

FIG. 12.—Diagram of potential drop on two-phase three-wire circuit.

**36. Two-phase line drop.** In the case of a **two-phase four-wire circuit** the drop is computed for each phase independently, using the method given in Par. **33** and Par. **34**, or the Mershon diagram, Par. **35**.

**In a two-phase three-wire system** having the load connected between the outer phase wires and the neutral or common phase wire, the inductive drop on the neutral produces an unbalanced pressure at the load or receiver end. This condition is illustrated in the diagram in Fig. 12. The ohmic and inductive drops on the outer wires are represented by the triangles $XYZ$ and $RST$. $ON$ represents the phase of the neutral current and $OCD$ represents the ohmic and inductive drops on the neutral conductor. The power-factor is assumed at 90 per cent. The voltage necessary to maintain normal pressure at the feeder end is represented by line $DZ$ on one phase and by $DT$ on the other phase. The net line drop is the difference between $DZ$ and $OX$ in one phase, and between $DT$ and $OR$ in the other. It is evident from the diagram that the drop on one phase is considerably greater than on the other. The difference varies with the power-factor and the size of the wire, being greater with larger sizes of wire. No simple rule can be laid down for calculating such problems, when the load is not equally balanced between phases, and a graphical solution is usually the most practical.

**37. Drop in three-phase three-wire symmetrical circuits.** In a three-phase three-wire circuit with conductors symmetrically arranged and carrying a balanced load, the inductive effect is the same in each wire and

* *American Electrician*, June, 1897.

Digitized by Google

the calculation of drop may be made exactly as it would be for a single-phase circuit carrying one-half the load.

As the currents in the three wires are 120 deg. apart in time phase, the ohmic drop for the two wires making up any one phase is not twice that of one wire, as it is in a single-phase two-wire circuit, but is 1.73 times this drop. The inductive component of drop is also 1.73 times that of a single wire, for the loop. If the load on a three-phase circuit were the same as on the single-phase circuit in the previous example (Par. 34), the current per wire in the three-phase circuit would be

$$\frac{100 \times 1.732}{3} = 57.7 \text{ amp.}$$

The drop at 100 amp. on the three-phase circuit would be $(5.8/2) \times 1.73 = 5.0$ per cent., and at 58 amp. the drop would be 58/100 of 5 per cent., or 2.9 per cent. The single-phase drop at the same load was found to be 5.8 per cent., or twice the three-phase drop.

Therefore, for the same load and equal line drop, the size of the conductor in a three-phase circuit may be one-half that of a single-phase circuit. There being three wires in the three-phase circuit, it follows that the *weight of copper which is required for a three-phase circuit is three-quarters of that required for single-phase* transmission, with equal pressures between phase-wires, equal loads and equal line drops.

**38. Drop in three-phase three-wire unsymmetrical circuits.** When the arrangement of conductors is not symmetrical, the inductive component of drop is different among the different pairs of wires, on account of the different distances between centres. The most common case is that in which the wires are arranged on a cross-arm in the same horizontal plane. In such cases the equivalent of a symmetrical arrangement can be secured by **transposing** the conductors at proper intervals. This is not necessary in 2,200-volt distributing feeders which are equipped with line-drop compensators, as they can easily be adjusted to correct the unbalanced conditions.

The calculation of drop in an unbalanced three-wire three-phase circuit is somewhat complicated and such problems are most readily solved graphically. Loads which are not unbalanced more than 10 per cent. to 15 per cent. may usually be averaged and considered as balanced for practical purposes. In systems where the lighting service is all on one phase, and the third phase wire carries a small scattered load of three-phase motors, the lighting phase may be considered as a single-phase circuit in computing the drop. However, as the motor load increases, the drop in the lighting phase becomes less for a given current value, until, when the current in the other phases equals that in the lighting phase, the drop in the latter is but 86.6 per cent. of what it would be with the same current carried for lighting service only.

**39. Drop in three-phase four-wire circuits.** The pressure at the transformer, on such systems, is the pressure between phase wires and neutral; when the latter is 2,200 volts, the pressure across phase wires is $2,200 \times 1.732 = 3,810$ volts. With **balanced load** the neutral conductor carries no current and the drop is that in the phase wires only. The resistance drop at 100 amp. on a No. 0 circuit 9,000 ft. long is $100 \times 9 \times 0.0981 = 88$ volts. This is 4 per cent. of 2,200 volts. Assuming a 12-in. spacing, single-phase, the inductive component of drop is $100 \times 9 \times 0.1043 = 94$ volts, or 4.3 per cent. At 80 per cent. power-factor, by the Mershon diagram (Fig. 11), the total drop is 5.8 per cent. The size of wire for a given load and drop, three-phase, is one-half what it would be for a single-phase circuit, or, assuming wires of equal size, the distance may be doubled for the same drop as compared with a single-phase circuit.

In the case of an **unbalanced four-wire circuit**, which is the more usual condition, the effect of the drop on the neutral wire must be taken into consideration. In general, the effect of the unbalance is to increase the drop on the more heavily loaded phases and decrease it on the lightly loaded phases, in comparison with the drops at balanced load, as shown in the case of the three-wire two-phase circuit above. A graphical solution of the problem of determining line drop in unbalanced three-phase four-wire circuits is shown in Fig. 13. This diagram is constructed on a principle similar to that used in Fig. 12 for a two-phase circuit.

The load on $A$ phase is heavier than that on $B$ and $C$, and the drop $OE$ due

Digitized by Google

to the neutral current is added almost directly to the drop *XZ* on the *A*-phase conductor.

The net drop on *A* phase is *EZ–OX*, that on *B* phase is *ET–OR* and on *I* phase it is *EW–OU*.

**Where line-drop compensators are employed** in each conductor, only the individual calculations for the four conductors are required, as the compensator corrects for the effect of the neutral drop.

**40. Skin effect** is an alternating-current phenomenon (Sec. 2, and Sec. 4, which materially affects cables of large cross-section, due to the fact that the currents passing through the strands around the outer surface of the cable encounter less inductance and impedance than the strands near the centre, thus causing the outer strands to carry more current, proportionately, than the inner strands. It is desirable, therefore, to build up large cables about a core of non-conducting material. Cables of over 500,000 cir. mils are often made in this manner where they are to be used in 60-cycle systems, and cables of more than 1,000,000 cir. mils for 25-cycle systems.

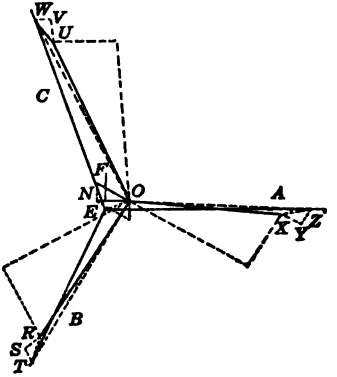

FIG. 13.—Diagram of drops in a three-phase four-wire circuit.

The increase in effective resistance due to skin effect is approximately proportional to the product of the frequency and the circular mils, as shown in the following table in Par. 41.

**41. Table of Skin-effect Coefficients**

| Cir. mils × frequency | Coefficient | |
|---|---|---|
| | Copper | Aluminum |
| 10,000,000 | 1.000 | 1.000 |
| 20,000,000 | 1.008 | 1.000 |
| 30,000,000 | 1.025 | 1.006 |
| 40,000,000 | 1.045 | 1.015 |
| 50,000,000 | 1.07 | 1.026 |
| 60,000,000 | 1.096 | 1.04 |
| 70,000,000 | 1.126 | 1.053 |
| 80,000,000 | 1.158 | 1.069 |
| 90,000,000 | 1.195 | 1.085 |
| 100,000,000 | 1.23 | 1.104 |
| 125,000,000 | 1.332 | 1.151 |
| 150,000,000 | 1.483 | 1.206 |
| 175,000,000 | 1.53 | 1.266 |
| 200,000,000 | 1.622 | 1.33 |

To determine the skin effect of a copper cable having an area of 1,000,000 cir. mils, carrying current at 60 cycles, refer to the table, opposite the product 60,000,000. The coefficient is 1.096. The resistance of a 1,000,000-cir. mils cable per 1,000 ft. being 0.01035, the effective resistance at 60 cycles is $0.01035 \times 1.096 = 0.01134$, or 9.6 per cent. more than with continuous current. The resistance of a 1,500,000-cir. mils cable is increased 19.5 per cent. at 60 cycles. The current-carrying capacity of large cables is reduced in proportion to the reciprocal of the skin-effect coefficient; that is, if the coefficient is 1.096, the capacity is only $1/1.096 = 91.2$ per cent. of that with continuous currents.

**42. Effect of electrostatic capacity.** At ordinary distributing voltages and frequencies the capacity effect is too small to be of any consequence in the solution of line-drop problems and need not be considered. At transmission voltages it is a matter of considerable importance in many cases (Sec. 11). The electrostatic capacity of an overhead circuit is fixed by the distance between the conductors and by their size; with insulated conductors (aerial or in cable), the capacity is further affected by the dielectric constant (Sec. 4), of the insulating material. The mutual capacity of a single-phase uninsulated circuit strung in the open air, per 1,000 ft. of circuit, is given by

$$C = \frac{0.003677}{\log \frac{d}{r}} \qquad \text{(microfarads)} \qquad (2)$$

where $d$ is the distance between centres of conductors and $r$ is half the diameter (radius) of the conductor. The logarithm used is the *common logarithm*.

**43. Charging current.** The charging current of a single-phase circuit is given by

$$I = \frac{6.284 DnCE}{1{,}000{,}000} \qquad \text{(amp.)} \qquad (3)$$

where $D$ is the length of circuit in thousands of feet, $n$ is the frequency, $C$ is the capacity in microfarads, and $E$ is the effective voltage between conductors. The charging current of a symmetrical three-phase circuit, between phase wires, is $2/\sqrt{3} = 1.155$ times that of a single-phase circuit with equal spacing between phase wires.

When an inductive load is carried on the line, the lagging component of the load current tends to offset the leading current required to charge the line. The tendency of the charging current to raise the power-factor of the line current thus results in a corresponding tendency to reduce the line drop where the load is of an inductive character. (For full treatment of the effect of capacity on line drop, see Sec. 11.)

**44. Electrostatic capacity of cables.** In underground cable work the effect of charging current is greatly increased by the reduced separation of the conductors. The charging current cannot be determined so easily, however, since the dielectric constant of the insulation must be taken into account. The mutual capacity of a three-phase three-conductor cable between conductors, per 1,000 ft., is given by

$$C = \frac{0.00735\ K}{\log \frac{3a^2\,(R^2 - a^2)^3}{r^2\,(R^6 - a^6)}} \qquad \text{(microfarads)} \qquad (4)$$

When $K$ is the dielectric constant, $a$ is the distance from the centre of the cross-section of the cable to the centre of the conductors, $R$ is the radius of the inside of the lead sheath, and $r$ is the radius of the conductors. The *common logarithm* should be used.

**45. Dielectric constants of cable insulation.** The value of $K$, the dielectric constant, is determined by tests on samples of cable. It varies with different materials, and with variation of temperature with the same material. The general effect of increase in temperature is to decrease the dielectric constant, and increase the dielectric loss. The length and the voltage of cable systems are usually such that the charging current is not sufficient to cause any operating inconvenience.

**46. Current-carrying capacity of conductors.** The energy absorbed by a circuit, $I^2R$, is dissipated in the form of heat, and tends to raise the temperature of the conductor. The maximum current-carrying capacity of a conductor is dependent upon whether it is installed in open air, in conduit or underground. The character of the insulation is also a factor, since certain kinds of insulation may be safely operated at higher temperatures than others.

The insulation of rubber-covered conductors should not be operated regularly at temperatures above about 50 deg. cent. (122 deg. fahr.). Weatherproof and other fibrous types of insulation may be operated at temperatures as high as 65 deg. to 70 deg. cent. (149 deg. to 158 deg. fahr.). Conductors used inside of buildings are subject to the requirements of the National

Digitized by Google

Electrical Code, which limits the current in rubber-covered cables to values such that the temperature rise will not exceed about 15 deg. cent. (59 deg. fahr.). This represents a temperature of about 40 deg. cent. (104 deg. fahr.) during summer months, or in parts of buildings such as engine rooms which are normally above outside air temperature. Slow-burning insulation is accordingly required in places where the temperature is likely to be above 45 deg. cent. (113 deg. fahr.).

**47. Table of Current-carrying Capacity of Wires and Cables Under Various Conditions**

| Size, A.W.G. or cir. mils | National electrical code | | Lead-covered cables | | |
|---|---|---|---|---|---|
| | | | Single conductor | | Three conductor paper ins. 45 deg. cent. rise. (amp.) |
| | Rubber ins. (amp.) | Slow-burning ins. (amp.) | Rubber 30 deg. cent. rise (amp.) | Paper or cambric, 40 deg. cent. rise (amp.) | |
| 14 | 15 | 20 | ..... | ..... | ..... |
| 12 | 20 | 25 | ..... | ..... | ..... |

**48. Current-carrying capacity of underground cables.** The rise of temperature of underground cables depends upon the amount of energy liberated by all the cables in the duct line, and upon the ability of the cables and ducts to radiate the heat to the surrounding earth. The laws governing the radiation of heat from cable conductor to lead sheath and thence to earth have been studied by various investigators. S. Dushman* has derived a a formula by which the temperature of the copper may be calculated from observations taken on the lead sheath, as follows:

$$t = K \log \frac{D}{d} \frac{(I^2 \times 1{,}000)}{(\text{cir. mils})} \text{ (deg. cent.)} \qquad (5)$$

in which $t$ is the fall of temperature in deg. cent. from copper to sheath, $D$ is the inside diameter of sheath in inches, $d$ is the diameter of the conductor (inches), $I$ is the current (amperes) and $K$ is a constant varying with the type of cable. For single-conductor cable, $K = 0.27$; for two-conductor cables $K = 0.6$; and for three-conductor cable, $K = 0.9$. The *common logarithm* is used.

The temperature of the conductor may thus be calculated from sheath

* Dushman. S. *Trans.* A. I. E. E.; Vol. XXXII, 1913, p. 165.

Digitized by Google

measurements without taking resistance measurements of the copper. This formula is of great practical value where cables cannot be taken out of service to make resistance measurements. Tests made on cables in service verify Dushman's formula with sufficient accuracy for practical purposes.

**49. The radiating capacity of cables in the central ducts** of a large underground line is less than that of the cables in the peripheral ducts, and the temperature of the former tends to become higher when the ducts are well filled. The effect of the position of cables in a duct line has been studied by H. W. Fisher.* The results of his tests indicate that with a nine-duct line the rating of a cable should be reduced about 15 per cent. from its capacity in a four-duct line; while in a sixteen-duct line it should be reduced about 40 per cent. This is true only when there are working cables in all the ducts of the line.

**50. The carrying capacity of multiple-conductor cables** is less than single-conductor cables of the same size, because of the larger energy loss in proportion to the radiating surface. Duplex cable has about 90 per cent. of the carrying capacity of single-conductor cable; concentric cable, 80 per cent.; and three-conductor cables, 75 per cent. The maximum temperature at which paper or cambric should be operated is about 65 deg. cent. (149 deg. fahr.). The temperature may be pushed above this figure occasionally for a short time, but if operated continuously above 65 deg. cent. the paper will be injured.

## SUBSTATIONS

**51. The function of a substation** is to convert energy received from a bulk-supply system, at the transmission voltage and frequency, to energy suitable for distributing purposes. The energy distributed may be in the form of direct current at the voltage at which it is utilised, or in the form of alternating current at a voltage suitable for general distribution through step-down transformers located at suitable points in the district served. The expense of installing and operating a substation must be justified by the saving made by the shortening of distributing feeders and the reduction in feeder losses incident thereto.

**52. Substation location. The distance between substations** depends upon the voltage of distribution and the density of the load. The average length of the distributing feeders should be such that the total investment in feeder conductors and substation equipment is a minimum.

**In low-tension systems** it is usually found desirable to locate substations approximately 1 mile apart, except in very congested districts where they are sometimes located less than 0.5 mile apart, on account of the very large loads to be carried.

**In 2200-volt alternating-current distribution,** substations may be spaced from 2 to 3 miles; in four-wire systems operating at 2,300–4,000 volts, they may be located from 4 to 6 miles apart, in scattered districts. In the outlying parts of the larger cities they are usually found from 2 to 3 miles apart on account of the density of the load.

**53. Substation classification.** Substations may be divided into three principal classes: (a) those in which transformers change the pressure from that used in transmission to the distribution voltage; (b) those in which frequency changers convert energy from one frequency to another and from the transmission voltage to the distributing voltage; and (c) those in which the transmitted energy is converted by synchronous converters to continuous current at low voltage.

**54. General features.** Each of these classes of substations (Par. 53) has certain elements which are common to all. Each is served by incoming transmission lines which are terminated in oil switches and connected thence to a high-tension bus system. One side of the converting apparatus is connected to the high-tension bus and the other side to two or more distributing busses. From these busses the outgoing feeders are taken off through suitable feeder switches, in conjunction with regulating apparatus.

**55. Substation building. The size of the lot and the dimensions of the building** should be such as to permit an arrangement of apparatus which will not be unduly crowded, and which will permit the installation,

* Fisher, H. W. *Trans.* A. I. E. E.; Vol. XXII, 1903, p. 440.

Digitized by Google

repair and maintenance of the equipment at minimum cost. Where further growth is probable, due regard must be had for subsequent extensions of building and equipment. Fireproof construction is warranted where continuous service is important.

**56. Bus-bar arrangement.** Fig. 14 shows a simple arrangement for a substation having one main line and one reserve line. Where the load is such that several direct lines are required, a **transfer bus** (Fig. 15) is very desirable. This permits the operation of any machine from any line and makes the reserve line available in case of the failure of any of the main lines.

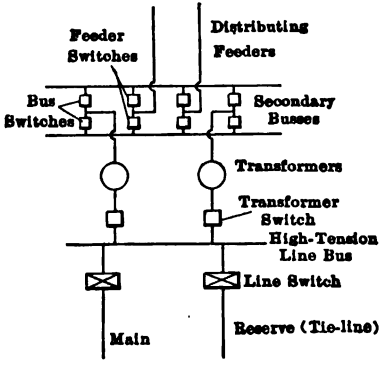

FIG. 14.—High-tension bus arrangement in a small substation.

**57. Duplicate distributing busses** are provided both as a means of operating the longer feeders at a higher bus pressure, and as a means of facilitating repair and maintenance work without interrupting service.

**58. In continuous-current systems, two busses are required** in practically all cases for **pressure control** during the heavy-load period, and in the larger substations it is sometimes necessary to provide **three busses** to take care of certain feeders which are exceptionally long or very short.

**59. Transformer substations.** The simplest type of substation is that which transforms alternating-current energy from one voltage to another

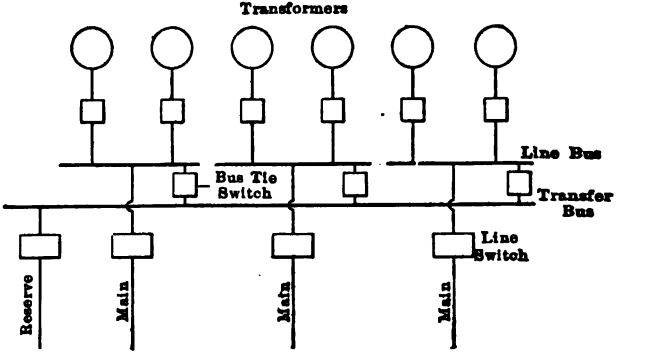

FIG. 15.—Bus arrangement in a large substation.

and requires, therefore, only transformers for the converting equipment. Both oil-cooled and air-cooled types of transformers are used for this purpose, with either single-phase or three-phase units. Oil-cooled units are preferable where the substation may be left without attendance during certain hours

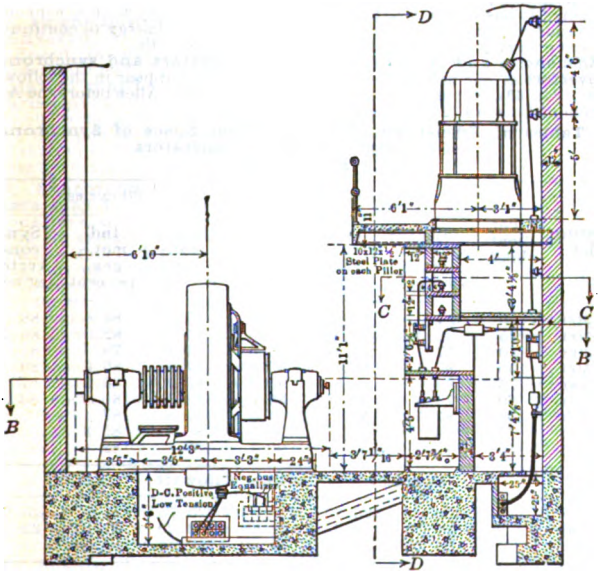
Digitized by Google

of the day. Oil-insulated, water-cooled transformers are used quite generally where there is an ample supply of cooling water.

**Single-phase units** are commonly employed where capacities of less than 1,000 kw. are required, although there is no settled practice in this regard.

**Three-phase units** are less expensive than single-phase units, particularly in the larger sizes, and require considerably less floor space.

**60. Frequency-changer substations.** Where the transmitted energy is converted to another frequency, the equipment consists of a motor generator, usually of the synchronous type; the motor is usually wound for the transmission voltage, to avoid the investment in transformers, where the voltage is less than 15,000 volts. This type of apparatus requires an exciter equipment, which may be driven by the machine itself, or by a separate motor. There should be at least one separately driven exciter equipment in a station where the exciters are direct connected.



Section *A-A* Incoming Line

FIG. 16.—Synchronous converter substation.

**61. The synchronising equipment** of frequency-changer sets must be so arranged that synchronising can be done at both frequencies. When the machine is brought into step on the transmission side, the arrangement of the poles is such that the generator end is held with a fixed angle of phase displacement from the supply system, except for one particular (and correct) position of the motor fields. In a 25-cycle to 60-cycle frequency changer having ten and twenty-four poles respectively, there are *five* positions in which the 25-cycle machine may come into synchronism, only *one* of which will permit the 60-cycle (generator) end to be synchronised with another frequency changer already in operation. The 60-cycle end must be synchronised by slipping poles until it comes into phase. Where the frequency changer is being synchronised with a generating system, it is necessary to advance or retard the phase of the 60-cycle generators.

Digitized by Google

**62. Continuous-current substations.** A continuous-current supply is usually derived from transmission systems by the use of synchronous converters, or motor-generators. The synchronous converter is universally employed where the transmission system is operated at 25 cycles, as the converter is less expensive in first cost and more efficient in operation than a motor-generator. Converters have been little used in 60-cycle systems until recent years. The development of the interpole converter has minimized the tendency of 60-cycle converters to hunt and flash over.

Where motor-generators are employed both synchronous and induction types of motors are in use. The induction motor has the advantage of greater stability than the synchronous motor in times of disturbance to the frequency or the voltage of the system. The induction motor, however, has a power-factor (lagging) of about 85 per cent., whereas the synchronous motor has an adjustable field and may be operated (overexcited) with a leading power-factor, thus raising the power-factor of the generating system. It has become customary, therefore, to employ both synchronous and induction types of motors in converting 60-cycle energy to continuous-current energy, in order to secure the advantages of both.

**Efficiencies and first costs of motor-generators and synchronous converters** at one-half, three-quarters, and full load appear in the following table (Par. 63), compiled from a paper read by E. W. Allen before the Association of Edison Illuminating Companies, 1908.

**63. Tables of Efficiencies, Cost and Floor Space of Synchronous Converters and Motor-generators**

**Efficiencies**

| Rating, kw. | Per cent. load | 25 cycles | | | 60 cycles | | |
|---|---|---|---|---|---|---|---|
| | | Syn. mot.–gen. per cent. | Ind. mot.–gen., per cent. | Syn. converter, per cent. | Syn. mot.–gen., per cent. | Ind. mot.–gen., per cent. | Syn. converter, per cent. |

**64. Motor-generator sets** are commonly wound for the transmission voltage, and are started by the use of a compensator at fractional voltage. A single compensator is sufficient for a substation if a starting bus is provided, through which the same compensator can be used to start any of the units; a spare compensator should be in reserve.

**65. The synchronous-converter substation,** Fig. 16, is provided with transformers stepping down to the proper voltage for the alternating-current side of the converter. The transformers are commonly of the air-blast, three-phase type, as this form of equipment can be placed in a minimum of space.

Digitized by Google

**66. Connection of neutral for three-wire continuous-current system.**—The six-phase type of converter, wound for 250 volts, with a diametrical connection in order to provide for the neutral conductor, Fig. 17, is commonly employed for machines of 1,000 kw. and larger. Motor-generators are also designed for 250 volts, a small **balancer-set** being used to take care of the unbalanced load.

**67. The regulation of pressure on the bus supplied by a synchronous converter** is accomplished by the use of an induction regulator placed between the transformers and the converter. Some variation in pressure can be secured by manipulation of the converter field-rheostat, but this affects the power-factor and it is not depended upon for pressure control.

**68. In the split-pole type of converter,** which has been introduced in recent years, considerable range of **pressure regulation may be secured** by variation of the field rheostat without serious interference with the power-factor, and with this type of machine regulators are sometimes omitted.

**69. Synchronous converters may be started** in various ways, and it is usual to provide for at least one method of starting from both the alternating-current and the continuous-current sides. The converter may be started from the continuous-current side by the use of a starting rheostat in practically the same manner as that used in starting a continuous-current motor.

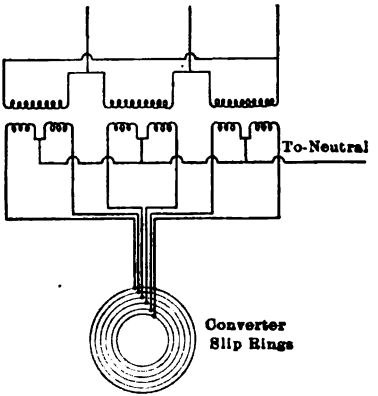

FIG. 17.—Six-phase diametrical connection for synchronous converter.

The converter may be started from the alternating-current side with the field open, by impressing approximately half the normal pressure, derived from a starting compensator or half-taps on the secondary of the transformer. The latter method is usually preferable. After the machine has come up to speed, the fields are excited and the polarity corrected, if necessary, by reversing the field, and slipping back one pole.

**The current required in starting** from the alternating-current side is from one and one-half to twice full-load current, while 25 per cent. to 30 per cent. of full-load current is sufficient for starting from the continuous-current side. The normal method of starting is, therefore, preferably from the continuous-current side.

**70. Low-tension switchboards.** The operation of distributing systems at low pressure involves very large currents and for that reason the most important part of a low-tension switchboard is the arrangement of heavy bars of copper, 3 in. to 6 in. wide and 0.25 in. to 0.5 in. thick, required for the safe handling of such currents. The important features of the design are to maintain sufficient clearance between bars of opposite polarity and to make the connections as short as possible consistent with accessibility for repair and maintenance work.

**71. Feeder panels.** The switchboard shown in Fig. 18 is based upon a vertical arrangement which permits ample separation of opposite polarities and minimum length of the bus-bar copper per feeder. Each vertical section comprises a set of switches and instruments for one three-wire feeder, the neutral not being brought into the main board. The neutrals are commonly carried to a separate bus in the basement, where they are connected without disconnecting switches other than removable copper links.

**72. Switchboard voltmeters.** It is customary to provide a single voltmeter with a multiple-point switch so arranged that one voltmeter can

Digitized by Google

be used to take the pressure readings on the pressure wires of any of the feeders. Separate voltmeters are provided to give continuous indications of the pressure on each bus.

**73. Switchboard ammeters** are provided in each side of outgoing feeders in order to give an indication of any excessive unbalance of the load. These are also required for each machine.

**74. Number of sets of busses.** Two sets are commonly required for proper distribution, one bus being operated at a higher pressure than the other. In the large substations it is sometimes desirable to operate as many as three busses.

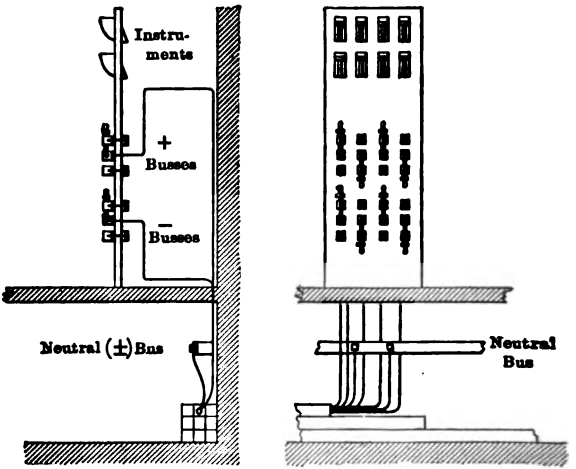

FIG. 18.—Low-tension feeder bus.

**75. Knife switches.** Single-pole, double-throw knife switches are provided for the control of the feeders, each feeder being so arranged that it can be thrown to either of two busses. This permits the longer feeders to be put on a higher-voltage bus at the time of the heavy load, thus maintaining an even pressure throughout the network.

**76. Boosters.** It is often necessary, in substations near the edge of the system, to maintain booster-sets which can be put in series with extra long feeders in order to maintain pressure at the distant end. Similarly, very short feeders are sometimes provided with resistances (equivalent to negative boost) to absorb part of the pressure. These resistances are made adjustable for two or three values, and must have ample radiating capacity to avoid overheating at full load. Strips of galvanized sheet-iron have been found very satisfactory for this purpose.

**77. Storage-battery reserve.** One of the principal advantages of continuous-current distribution is the possibility of having a storage-battery reserve. In order to be of the greatest value, the battery reserve should be distributed in a number of individual units located at central points in the system, so that it can act as a reserve in case of the failure of the supply in any part of the system.

**78. Battery rooms.** On account of the evolution of gases, and the presence of acid vapor, it is necessary that the portion of the building occupied by the battery be provided with ample ventilating facilities and that all metal work be covered or painted as well as possible.

Digitized by Google

**79. End-cell switches for battery reserve.** The tendency of the battery pressure to fall off at the time of discharge is provided for by the use of end-cell switches which are under the control of the operator, so that additional cells can be connected in series in sufficient number to hold the pressure up to the desired value. Normally, the end-cell switches are set so that the battery floats on the system. In any emergency which causes the bus pressure to drop, the battery immediately begins to supply energy, thus tending to maintain the bus pressure. A diagram of a battery, equipped to act as a reserve on two sets of busses, is shown in Fig. 19.

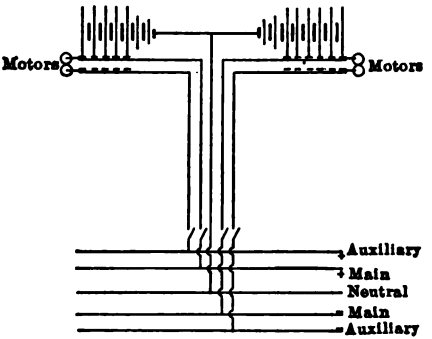

FIG. 19.—Arrangement of battery end-cells.

**80. High-tension switchboards (up to 15,000 volts).** In the design of high-tension switchboards, the space required for proper separation and insulation of the bus bars, and for the installation of oil-switches, necessitates an arrangement in which the busses and oil-switches are installed in some remote location such as a basement, the control panels being located at a point convenient to the operator.

**Ammeters, voltmeters and wattmeters are operated** with series (current) and shunt (potential) transformers, and oil-switches are usually of the remote-control type, so that the switchboard panel carries only low-tension apparatus. In smaller substations and in cases where only a few switches are installed, hand control is sometimes employed for the oil-switches on outgoing feeders.

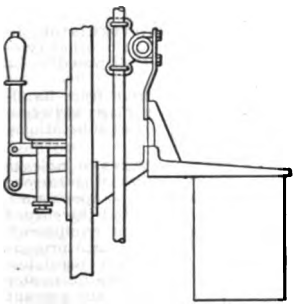

FIG. 20.—Tank-type of oil-switch.

**81. High-tension bus bars** commonly consist of cable or copper tubing mounted on suitable insulating supports, carried on a skeleton frame of pipe or angle iron. Oil-switches for distributing feeders are commonly mounted on the same framework in such a way as to provide an orderly system of connections from the busses to the switch terminals. Bus bars operating at voltages of 6,600 and upward are commonly installed in compartments, so arranged as to reduce to a minimum the probability of an arc between conductors of opposite polarity; this is very important where large amounts of energy are available to supply a short-circuit in case it should occur.

**82. Disconnect-switches** should be provided to permit oil-switches to be taken out of service during repair and maintenance work.

**83. Two general types of oil-switches** are employed, the **tank type** (Par. 84) for distributing-feeders and for the control of converters or transformers, and the **compartment type** (Par. 85) which is used for the control of transmission lines and at other points in the transmission system where the switch may be called upon to open automatically under short-circuit.

Digitized by Google

**84. The tank type of oil-switch,** Fig. 20, is made in single-pole, two-pole, or three-pole construction, with individual tanks which separate the opposite polarities.

**85. The compartment type of oil-switch,** Fig. 21, is made on a very much larger scale, each pole of the switch being enclosed in a separate compartment of brick or concrete. The front of the compartment is closed by fireproof doors which are hinged at the top to permit heated gases to escape readily, in case they should be liberated in connection with the operation of the switch on a very heavy short-circuit.

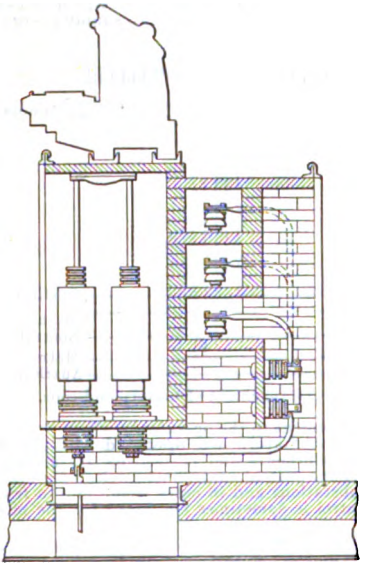

FIG. 21.—Compartment type of oil-switch.

## PRESSURE REGULATION

**86. Potential regulators.** The distributing feeders should be equipped with potential regulators in order to provide proper distribution of pressure. Two types of potential regulators are in general use, one of which consists of a transformer with a switch in the secondary so arranged that approximately 10 per cent. of the bus pressure may be added to, or subtracted from (step by step), the bus pressure. In another type, the secondary of a transformer is mounted on a movable core (Sec. 6), so arranged that more or less of the magnetic flux may be passed through the secondary winding, and the pressure thus raised or lowered by inductive action. The latter is called the **induction regulator** and is preferable to the other type on account of the absence of sliding contacts, which are disposed to be troublesome in operation.

**Regulators may be controlled** by hand, by motor-drive from hand-operated switches, or by motor-drive from automatically operated switches. The extra expense of automatic control is justified, in important substations, by the improved service given.

**87. Line-drop compensators.** The use of **pressure wires** to indicate the pressure at the end of a feeder is not necessary on alternating-current feeders, since they can be regulated by the use of line-drop compensators. The length of alternating-current feeders is usually so great that the cost of pressure wires is more than the cost of the compensator equipment. In principle, it consists of a miniature circuit containing the same proportion of resistance and inductance as the feeder circuit which it regulates. The drop in this resistance and inductance is inserted in the voltmeter circuit in such a manner as to reduce the voltmeter reading by the amount of the feeder drop. The amount subtracted from the voltmeter reading the line-drop compensator is directly proportional to the load carried by the circuit and to the power-factor, so that the voltmeter gives a correct indication of the pressure at the feeder-end at all loads, when the line-drop compensator is once properly adjusted.

**88. The Westinghouse line-drop compensator,** Fig. 22, is designed to provide for a drop of 24 volts with a load of 100 amp. The current from the secondary of the series (current) transformer *S* passes through the induc-

Digitized by Google

tive section *B* and the non-inductive section *A* in proportion to the load on the feeder. The secondary winding is divided into four sections of 5 volts each, and four sections of 1 volt each. The 5-volt terminals are connected to the contacts numbered 1, 2, 3, 4, and 5, and the one-volt terminals to the contacts numbered 6, 7, 8, 9, and 10. The arms may be independently adjusted, thus permitting any setting from 1 volt to 24 volts. The current from the shunt (potential) transformer *C* passes through the feeder voltmeter and the two movable arms to 3, thence through the portion of the non-inductive section, which is included between 3 and 5, and the portions of the inductive section between 6 and 9 and between 4 and 5, back to the transformer *C*. In completing this circuit, the impressed pressure has been opposed by a counter-e.m.f. of 10 volts in the non-inductive section and by 8 volts in the inductive section. The reading of the voltmeter is thus made

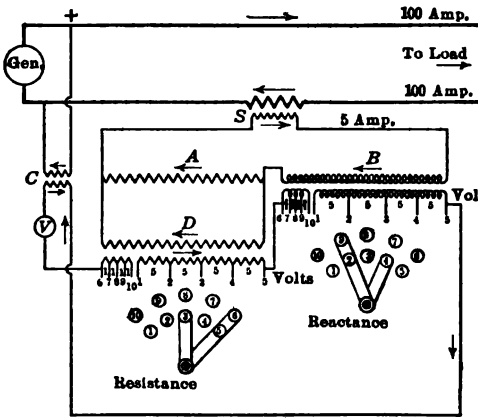

FIG. 22.—Circuits of Westinghouse line-drop compensator.

the same as it would be at the end of a feeder (in the secondary) having a resistance-drop of 10 volts (secondary) and a reactance-drop of 8 volts (secondary) at 100-amp. load.

**89. In the General Electric line-drop compensator,** Fig. 23, there is but one movable arm on each section, with eight points per section. Each point represents 3 volts when 1 amp. is flowing in the compensator circuit. The compensator shown (Fig. 23) is set so as to introduce in the voltmeter circuit an inductive counter-e.m.f. of 9 volts and a non-inductive counter-e.m.f. of 12 volts, when the feeder is carrying 100 amp.

**90. Calculation of compensator setting for a single-phase feeder.** Given a 60-cycle feeder of No. 0 A.W.G. copper wire, 5,000 ft. long, single-phase, wires 12 in. apart, series (current) transformer ratio 100 amp. to 5 amp., shunt (potential) transformer ratio 2,200 volts to 110 volts, how should the compensator be set?

The resistance drop on No. 0 wire, from Par. **31**, is 0.0981 volt per amp. per 1,000 ft.; hence the drop at 100 amp., for 5,000 ft., will be $2\times100\times5\times0.0981=98$ volts $=4.5$ per cent. The inductive drop of No. 0, at 12-in. spacing, being 0.1043 volt per amp. per 1,000 ft., the drop at 100 amp. will be $2\times100\times5\times0.1043=104$ volts $=4.7$ per cent. The resistance and the reactance should each be set at 5 volts ($=0.045\times110$), to give constant pressure at the end of the feeder at all loads.

**91. Calculation of compensator setting for two-phase feeders.** In the case of **a two-phase, four-wire feeder,** the method of connection is

Digitized by Google

similar to that used for a single-phase feeder, except that separate equipment is required for each phase, and hence the calculations are similar.

A **two-phase, three-wire feeder**, with unbalanced load requires one compensator in each wire, with connections as shown in Fig. 24. The values of resistance and inductance per 1,000 ft. used in the case of a single-phase feeder are based on the use of two wires, whereas in a three-wire feeder each compensator corrects the drop in one wire only.

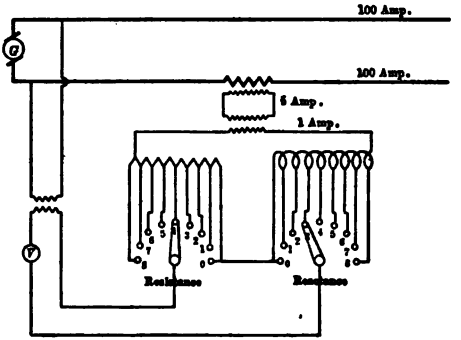

FIG. 23.—Circuits of General Electric line-drop compensator.

**92. Calculation of compensator setting for three-phase feeders.** In the case of a **three-phase, three-wire feeder** carrying unbalanced load, a compensator is required in each wire. For instance, if the feeder previously used for illustration were a three-phase, three-wire feeder (with symmetrical spacing of phase wires) carrying 100 amp. per wire, the ohmic drop in each wire would be $5 \times 100 \times 0.0981 = 49$ volts, and the inductive drop 52 volts.

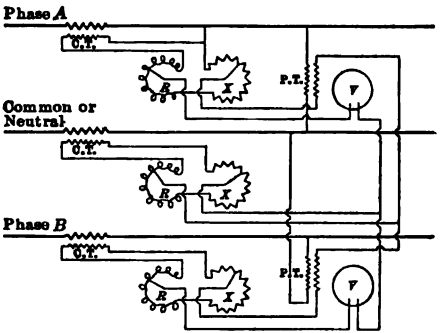

FIG. 24.—Compensator connections for two-phase three-wire system.

These values are respectively 3.8 per cent. and 4.1 per cent. of the pressure to neutral, 1.270 volts ($= 0.577 \times 2{,}200$).

In a **three-phase, four-wire feeder** operating at 2,200 volts between phase wires and neutral, the method of calculating the drop is as follows: Given a feeder of four No. 0 wires (12-in. spacing) running 5,000 ft. from the station as a three-phase feeder, the drop in each phase wire at 100 amp.

Digitized by Google

will be 49 volts, ohmic, and 52 volts, inductive. The working pressure being 2,200 volts, this is about 2.5 per cent. If the entire load of the feeder is delivered from this centre of distribution, the compensator on each phase wire

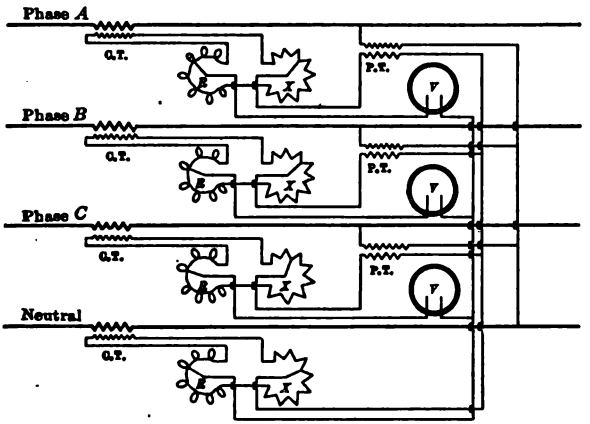

FIG. 25.—Compensator connections for three-phase four-wire system.

should be set at 2.5 per cent. on each dial; that on the neutral should be set at 2 per cent. on each dial, to take care of unbalanced load. If, however, the $A$-phase branches off with a neutral to a single-phase centre of a distribution 2,500 ft. beyond, there must be added to the $A$-phase setting, $2 \times 100 \times 2.5 \times 0.098 = 49$ volts $= 2.2$ per cent., making the new setting $2.5 + 2.2 = 4.7$ per cent. If the other phases branch to similar centres of distribution, at different distances, the drops must be computed similarly, and added to the three-phase drop. The connections of the compensators for a three-phase, four-wire feeder are shown in Fig. 25.

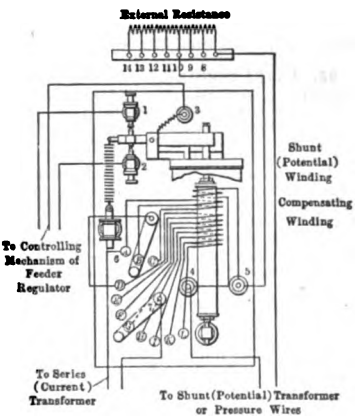

FIG. 26.—Automatic regulators for controlling feeder voltage.

**93. Automatic regulation of feeder voltage.** In connection with automatic regulation the General Electric Co. has developed a device which serves as a line-drop compensator combined with a relay. This device, known as a **"contact-making voltmeter,"** is shown in Fig. 26. It consists of a solenoid having windings which are tapped at various points and brought out to adjustable switches, as in the line-drop compensator. One winding produces a magnetic flux proportional to the pressure; another carries current in proportion to the load and opposes the flux due to the feeder pressure. This counter-

Digitized by Google

magnetomotive force may be adjusted roughly by setting the proper switch on the points *A*, *B*, or *C*, and the finer adjustments are made by the points *D* to *L*. The pivoted bar carries the contacts which control the supply of energy to the feeder regulator.

As the load increases, the plunger falls until the contact is made which raises the pressure on the feeder. This increases the flux due to the pressure and the plunger rises sufficiently to stop the movement of the regulator until a further change in load or bus pressure occurs. This device gives very satisfactory results at all power-factors from 75 per cent. to 100 per cent.

**94. Bus-bar voltage regulation.** Where there is a variable motor load supplied by motor-generator converting equipment, it is desirable to maintain a constant bus pressure, in order to prevent the load variations from affecting the bus pressure and thus impairing the steadiness of voltage on the feeders supplying the lighting service. The automatic regulator devised by Tirrill has been successful in accomplishing this purpose.

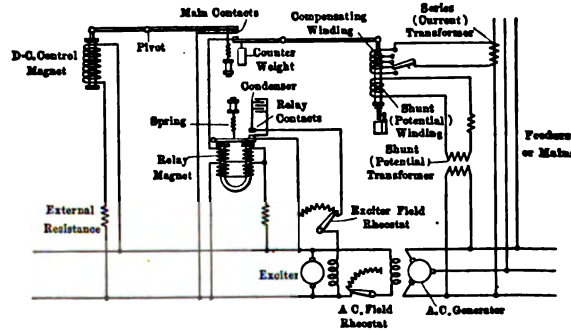

FIG. 27.—Connections of Tirrill regulator.

**95. Tirrill regulator.** The general scheme of connections is shown in Fig. 27. The secondary circuits of the shunt (potential) and series (current) transformers in the generator leads are connected through a solenoid in a compounding relation. The series section is subdivided so that different rates of compounding may be secured. A movable plunger is actuated by this solenoid, which in turn actuates a counterweighted lever, the opposite end of which is equipped to make electrical contact in a relay circuit. The other contact terminal of this relay circuit is carried on a similar lever which is actuated by the plunger of a direct-current solenoid. This solenoid receives current in proportion to the pressure at the exciter terminals. The relation of these contact-making levers is such that increased pressure at the exciter brushes tends to open the relay circuit, while increased pressure at the main generator terminals tends to close it.

This closing of the circuit demagnetizes the relay, which is differentially wound, and its armature is withdrawn by a spring. This shunts the field rheostat of the exciter, increases its terminal pressure, and opens the relay circuit, thus weakening its pull.

Where there are several units in parallel in a station, the regulator may be applied to the exciter for a portion of them and the bus regulated for constant pressure with the series coil of the alternating solenoid cut out. With this arrangement, the bus pressure may be maintained constant at any desired value by the insertion of an adjustable resistance in the pressure circuit of the alternating solenoid.

## SECONDARY DISTRIBUTION

**96. The secondary mains of an alternating-current system** serve users in a local area, while the primary mains supply larger areas. The standard system of secondary distribution in America is the **single-phase,**

Digitized by Google

**three-wire Edison system** at approximately 110–220 volts for lighting and small motor service, and 220-volt two-phase or three-phase for general motor service; 440 volts and 550 volts are also used to some extent for power systems in industrial plants. For the supply of mixed service of lighting and motors from a secondary network, the **four-wire, three-phase system** at 115–200 volts or 120–208 volts, approximately, is sometimes used.

**97. The voltage of general distribution systems** must be low enough to be adapted to incandescent lamps, fans, heating devices and other small accessories, which are preferably made for the voltages around 110. Motor voltages are higher in order to secure economy of conductor investment; this is especially true with large installations.

**98. Transformers are usually wound for a ratio of 2,200 to 110–220 volts,** though some of the systems where 115–230 volts are standard are using a ratio of 2,080 to 115–230 volts. This secondary voltage permits a spacing between transformers of 600 ft. to 800 ft.

**99. In laying out secondary systems for lighting service, it is usual to limit the drop from transformer to consumer to about 2 per cent.** where first-class service is required. In scattered districts where secondaries are too small and remote to warrant interconnection, the problem of design consists in striking a balance between the cost of conductors, and the cost of transformers and their losses.

By reaching out farther from the transformer with the secondary mains, the number of transformers is reduced, and, their average size being larger, their total cost is smaller. This is true because the cost per kilowatt is less for the larger sises, and because the kilowatt capacity required per kilowatt connected is less for a large number of users than for a few.

**100. Minimum annual cost.** As the radius of distribution from the transformer becomes more than 500 to 600 ft., the cost of conductors increases very rapidly, and it becomes more economical to provide additional transformers. On the other hand, if too many transformers are used, the iron loss which goes on 24 hr. a day becomes excessive, and the investment per kilowatt in transformers is high. The minimum annual cost of a secondary system is that at which the fixed charges on conductors and transformers, plus the value of the iron loss, is a minimum. The iron and copper losses of standard American transformers appear in the table in Par. **101** (also see Sec. 6).

**101. Losses and Efficiencies of Standard Transformers for Alternating-current Distribution**
2,200 to 110–220 volts, 60 cycles

| Rating kv-a. | Watts loss | | Per cent. efficiency, full load | Per cent. regulation | | Per cent. charging current. |
|---|---|---|---|---|---|---|
| | Core | Copper at 125 deg. fahr. | | 100 per cent. p-f. | 80 per cent. p-f. | |
| 1 | 20 | 26 | 95.8 | 2.61 | 3.18 | 5.5 |
| 1 1/2 | 25 | 37 | 96.2 | 2.47 | 3.10 | 4.0 |
| 2 | 30 | 46 | 96.5 | 2.33 | 3.00 | 3.6 |
| 3 | 34 | 70 | 96.8 | 2.36 | 3.01 | 3.0 |
| 5 | 40 | 82 | 97.2 | 2.08 | 3.12 | 2.5 |
| 5 | 45 | 102 | 97.3 | 2.08 | 3.10 | 2.3 |

**102. All-day efficiency of transformers.** In a distribution transformer, the iron loss may reach a considerable percentage of the daily consumption of energy. A 5-kw. transformer which carries full-load 4 hr. a day delivers 20 kw-hr. per day, and has a copper loss of about 102 watts at full-load, while the iron loss would be about 45 watts. The copper loss per day would be about 410 watt-hr., while the iron loss would be $24 \times 45 = 1{,}080$ watt-hr. The total loss being 1.5 kw-hr., the all-day efficiency is $20/21.5 = 93.0$ per cent., and the full-load efficiency is $5{,}000/5{,}150 = 97.1$ per cent. It is apparent that the all-day efficiency varies with the **load factor** or hours' use of the maximum load.

**103. Calculation of secondary mains.** The most economica size of conductor and spacing between transformers for secondary mains may be determined approximately as follows:* assuming a load density per 1,000 ft. and an allowable pressure drop, determine the distance between transformers which will result in that drop with several sizes of conductor.

The investment in wire and transformers may then be found. The fixed changes in the investment plus the annual value of the iron losses in the transformer constitute the annual cost of this secondary main (exclusive of pole line or conduit). The minimum annual cost will be found to work out approximately as in the curves shown in Fig. 28.

**104. Curves of cost variation, overhead distribution.** The variation of the elements of cost as the spacings between transformers and the size of wire are changed, is illustrated by the curves in Fig. 28, which are based upon a load density of 50 kw. per 1,000 ft., with overhead lines. It is apparent from this curve that the minimum cost is found with No. 2 wire at a spacing of 600 ft. between transformers. The curves of total cost at other load densities are shown in Fig. 29.

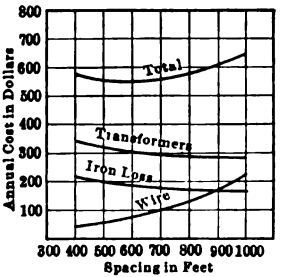

FIG. 28.—Elements of cost of secondary main.

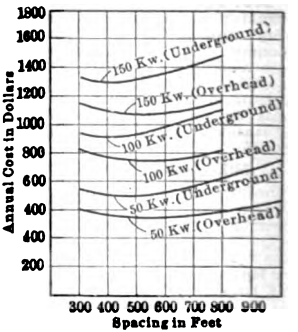

FIG. 29.—Economical spacing of transformers.

Where energy may be charged at less than 1 cent per kw-hr., or with water power, the decreased value of core loss tends to permit the use of smaller transformers, shorter spacings and a smaller size of wire.

**105. Curves of cost variation, underground distribution.** The curves for underground lines also appear in Fig. 29. The spacing for minimum cost is not materially changed, being about 500 ft. for each load density.

The flatness of the curve of total cost allows considerable flexibility in spacing, and it is generally preferable to use as few transformers as possi-

*Gear and Williams. "Electric Central Station Distributing System," p. 108.

Digitized by Google

ble with the larger sizes of conductor, so as to reduce the number of units to a minimum. Furthermore, it is usually desirable to **anticipate an increase in load** by installing a larger conductor than is required for immediate needs. The size of transformers is then gradually increased, from time to time, as the load increases.

**106. Uneven load density.** The curves (Figs. 28 and 29) are based on an assumption that the load is uniformly evenly distributed along the line throughout its length, but such is rarely the case in practice. At occasional intervals, department stores, churches or other large customers of energy throw heavy loads upon the line. It is necessary, therefore, to locate transformers near such large consumers' premises and design the mains between them to carry the scattered load.

**107. Secondary networks.** The gradual extension of mains on all streets results in a system of lines which is interconnected and becomes a network. **Transformers are preferably located** at intersections where they feed in all directions with the best economy of copper. In the design of such networks the sizes of secondary cable are fixed by the local conditions. The smaller consumers distributed along the routes are carried from mains of proper size, and the larger consumers such as theatres and department stores are cared for by a separate installation of transformers in the immediate vicinity of the consumers' premises.

**108. Underground construction is often required in networks** and this necessitates **manholes** of ample size for large transformers and such junction boxes as are necessary for operation. The space required is somewhat difficult to secure on account of pipes and other underground systems which limit the available space. In some cases it has been found desirable to install the transformers in a substation, supplying the network through low-tension feeders; this arrangement permits a saving in transformer investment and iron losses, as the diversity factor is better and the units are larger, but the cable investment is considerably greater.

**109. Separate transformers for large motor loads.** The design of secondary systems is subject to restrictions when **inductive loads,** such as arc lamps and motors, must be served along with incandescent lighting. The heavy starting-current required by induction motors may momentarily overload the transformer and the secondary main. This causes a flickering of incandescent lamps served in the vicinity. It is necessary, therefore, to install separate transformers for installations of motors if the best regulation is required for incandescent lighting. Motors larger than 10 h.p. can not usually be supplied from a lighting network without interfering with the service.

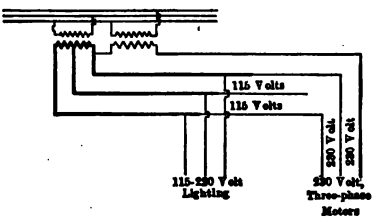

FIG. 30.—Three-phase secondary system, with single-phase lighting service.

**110. Three-phase supply for mixed loads.** In three-phase systems several methods of carrying mixed lighting and motor loads are in use. The most common method consists of **star-connected transformers supplying a four-wire main** operated at about 115 volts from phase to neutral and 200 volts across phase wires. The smaller lighting services are made three-wire and connected to two phases and neutral, and large services are balanced on three phases. Four-wire service is required wherever both lighting and motor service are supplied.

In another method, illustrated in Fig. 30, all the lighting is carried single-phase from a three-wire Edison main. Motors are served by the installation of additional smaller transformers and a fourth secondary (phase) wire. The lighting load is easier to keep balanced, and the higher diversity factor requires somewhat less transformer capacity for lighting.

**111. Determination of transformer capacity.** The selection of the size of transformers for various classes of consumers is important, since

Digitized by Google

excess capacity involves idle investment and unnecessary core losses. Very few consumers use their entire connected loads at any one time. Where a number of consumers are served by one transformer, the various *maximum demands do not occur simultaneously* and therefore the resultant maximum demand is less than the sum of the individual demands. The demand must be ascertained by measurements which may be made by means of an ammeter or by a **Wright demand** indicator (Sec. 3).

Certain **ratios of maximum demand to connected load** may be established by a series of such measurements for the various classes of consumers for which it is necessary to select transformers. These ratios or **demand factors** (Par. **112** to **118**) may then be applied with reasonable accuracy to the transformers for new consumers. The results of tests made on various groups of consumers in Chicago appear in Par. **112**.

**112. Table of Demand Factors in Lighting Service**
(Based on Chicago Experience)

| Description of load | Number of customers | Kilowatts connected | Kilowatts demand | Demand factor (%) |
|---|---|---|---|---|
| Residence | 137 | 84.7 | 18.9 | 22.3 |
| Residence | 68 | 126.6 | 15.75 | 12.4 |
| Residence (119 kw.; stores 11 kw.) | 196 | 129.5 | 28.85 | 22.3 |
| Residence (1 customer, 7.5 kw.) | 5 | 10.3 | 9.45 | 92.0 |
| Residence 70 kw.; stores 7 kw. | 77 | 77.0 | 21.0 | 27.3 |
| Residence (59.7 kw.; hotel 48 kw.) | 66 | 107.7 | 26.25 | 24.3 |
| Residence (1 30-amp. rectifier) | 121 | 183.5 | 30.5 | 16.6 |
| Residence | 34 | 47.5 | 10.5 | 22.2 |
| Residence (2 30-amp. rectifiers) | 19 | 79.2 | 15.7 | 19.8 |
| Residence (1 30-amp. rectifier) | 21 | 67.7 | 13.6 | 20.2 |
| Residence (1 30-amp. rectifier) | 21 | 54.1 | 13.1 | 24.3 |
| Residence | 47 | 68.7 | 8.4 | 12.2 |
| Residence | 144 | 129.95 | 22.6 | 17.4 |
| Residence (4 30-amp. rectifiers) | 43 | 59.0 | 26.6 | 42.0 |
| Residence | 85 | 99.65 | 16.1 | 16.1 |
| Residence | 84 | 112.5 | 14.7 | 13.2 |
| Residence, 20 kw.; Stores 15.7 (hotel 25 kw.) | 38 | 60.7 | 27.3 | 45.0 |
| Residence | 99 | 59.0 | 8.4 | 14.2 |
| Residence | 89 | 100.45 | 13.7 | 13.6 |

**113. In store lighting the maximum demand** for window lighting, signs and other display lighting is from 90 per cent. to 100 per cent. of the connected load. The demand on interior store lighting is from 50 per cent. to 70 per cent.

**114. In residence lighting** where the connected load is fifty lamps or less, the average demand factor of a group of residences is from 15 per cent. to 20 per cent. of the connected load; small residences and apartments having connected loads of forty lamps or less, average about 20 per cent. of the connected load.

**115. In theatre lighting** the border lamps and foot lamps, of several colors, are not used simultaneously; and the stage and the auditorium are not lighted simultaneously except for a very few minutes at a time. In a small theatre the demand factor may be from 70 per cent. to 85 per cent., while in a large theatre it frequently runs as low as 50 per cent.

**116. Influence of number of consumers on demand factor.** In general, a higher ratio must be used where but few consumers are served from one transformer, than where there are more, as the occasional maximum demands of individual consumers are proportionately much larger.

**117. The selection of transformers for motor loads** is more difficult, as the maximum load may vary greatly from day to day or from month to month. Elevator and crane motors require transformers having 100 per cent. to 125 per cent. of the rated motor capacity, unless there are several motors

Digitized by Google

supplied by one unit. This is necessary in order to hold up the pressure in starting. The average demand factors in motor service in Chicago are given in Par. 118. These figures were made up from several thousand installations of continuous-current motors in Chicago, which were equipped with maximum-demand meters.

**118. Table of Demand Factors in Motor Service**
(Based on Chicago Experience)

| Total installation in h.p. | Number of customers | Total h.p. connected | Average maximum h.p. | Ratio of max. to conn. h.p. |

## SPECIAL METHODS OF TRANSFORMATION

**119. General.** The use of various primary and secondary voltages and systems gives rise to situations, at times, which require the distribution engineer to make use of special methods of transformation. Some of the combinations of apparatus and connections which are most likely to be used are presented herewith.

**120. The connections of standard transformers** are made with two primary and two secondary coils, which permits their use on 2,200-volt or 1,100-volt circuits. The secondary may be connected for 110 volts or 220 volts, or on the three-wire Edison system at 110–220 volts. Some systems use a transformer having windings for 1,040–2,080 to 115–230 volts.

**121. Booster transformers.** Where it is desired to raise or lower the pressure by a fixed percentage, as when line drop is excessive, this may be accomplished by a transformer used as a booster. This is a transformer so connected that the secondary is in series and in phase with the main line and thus the primary pressure is raised by the amount of the secondary voltage, as shown in Fig. 31.

When the secondary is reversed, the transformer becomes a "choke," or **negative booster** depressing the line pressure instead of raising it. The connections for 5 per cent. and 10 per cent. "boost" are shown in Fig.

Digitized by Google

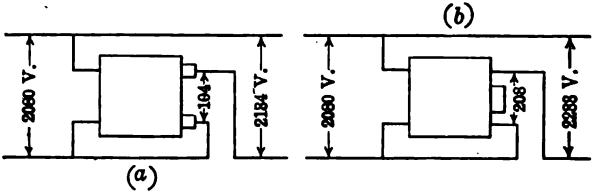

FIG. 31.—Booster transformer connection for positive boost.

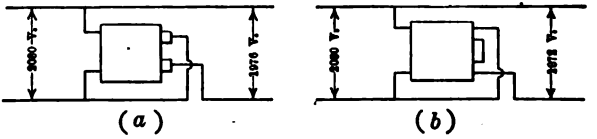

FIG. 32.—Booster transformer connections for negative boost or choking.

31, at *a* and *b* respectively. The corresponding connections for 5 per cent. and 10 per cent. choke (negative boost) are shown in Fig. 32.

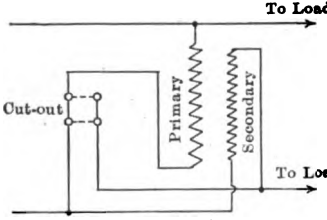

FIG. 33.—Connections of booster cut-out.

It is to be noted that the transformers used in these illustrations have a ratio of 10 to 1 or 20 to 1, and these percentages apply only to boosters having this ratio of transformation. If boosters having a ratio of 2,080 to 115–230 are used, the percentages are increased to about 5.5 per cent. and 11 per cent., respectively.

**122. Precautions when installing boosters.** If the primary of the booster is opened while the secondary is carrying the line current, the booster acts as a series transformer. The primary coils then generate a potential of 10,000 volts to 20,000 volts, or more, depending upon the load carried by the main circuit at the time. If a fuse is used in the primary, the blowing of the fuse will create this condition and the arc will hold across the terminals of the block, and is quite sure to break down the insulation of the primary coil.

The safest method of connecting or disconnecting a booster is to have the main line open while connecting it in or out of circuit. If the service cannot be interrupted, or if it is desired to switch the booster in or out at certain times, this may be accomplished by the use of a **series cut-out**, connected as shown in Fig. 33. The cut-out simultaneously opens the primary and short-circuits the secondary of the booster. Standard series-arc cut-outs should not be used where the line current is likely to be over 25 amp.

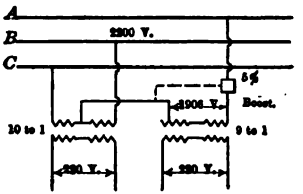

FIG. 39.—Transformation from three-phase to two-phase, or *vice versa*, with tee-connection.

Digitized by Google

**123. The use of boosters in a delta-connected three-phase system** is not so simple as in single-phase circuits. The booster secondary is looped into the line and pressure is taken for the primary from an adjoining phase, as in Fig. 34. The insertion of a booster on one phase affects the pressure on two phases, as shown diagrammatically in Fig. 35. The effect of a booster in each phase is shown in Fig. 36. Three boosters are required, therefore, to keep conditions in balance, in a three-phase three-wire circuit.

**124. Auto-transformers.** The use of 110-volt incandescent lamps in a 220-volt or 440-volt alternating-current system may be accomplished quite readily by the use of standard transformers used as auto-transformers. The connections in Fig. 37 show the methods of deriving two-wire and three-wire 110-volt distribution from a 220-volt system. When the lighting service is handled on a three-wire basis at 110–220 volts, the transformer carries only the unbalance of current; the primary winding is not used. Where 110-volt service is desired from a 440-volt plant, it may be secured from two transformers connected in series on the 220-volt side and in parallel on the primary side.

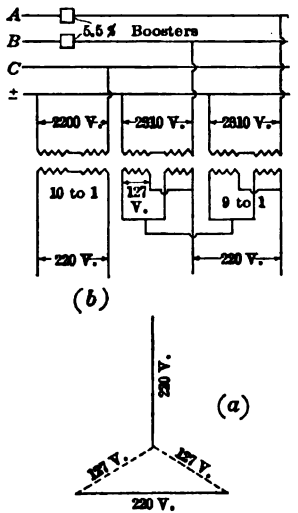

FIG. 40.—Two-phase service derived from a three-phase four-wire system with three transformers.

**125. Three-phase conversion with two transformers.** The cost of transformers for small three-phase motor service makes desirable the use of schemes of connections by which the three-phase secondary service may be derived from two transformers. Two schemes of connections are possible for this purpose, one known as the open delta and the other as the tee-connection.

The **open-delta connection** is merely an ordinary delta connection with one transformer left out (Sec. 6). Fig. 38 shows the open-delta connection supplied from a **three-phase four-wire** system. In this case the primaries are connected to two-phase wires and the neutral wire. In the open-delta connection the current in the transformer coils is 15.4 per cent. larger than with three transformers.

In the **three-phase three-wire** system, service may be given from two transformers with the **tee (T) connection** (Sec. 6). The current overload is 15.4 per cent.; as with the open-delta connection. This scheme cannot be used with standard 2,200-volt transformers on a four-wire system, as the principle of operation requires that the current divide and pass each way from the midpoint of the winding of one of the transformers, so that the magnetic field of one part balances the other.

**126. Conversion from three-phase to two-phase, or vice versa.** The **tee-connection** may be used in transforming from three-phase to two-phase, or *vice versa*, as shown in Fig. 39. with standard transformers having ratios of 9 to 1 and 10 to 1 respectively. If transformers having a ratio of 10 to 1 are available only, the right-hand transformer (Fig. 39) should be given a positive boost of 15 per cent. instead of 5 per cent. When using transformers having ratios of 9 to 1, the left-hand unit should be given a 10 per cent. negative boost, and the right-hand unit a 5 per cent. positive boost, in order to give 220-volt two-phase service from 2,200-volt primary mains.

**127. Two-phase 220-volt service from a three-phase four-wire system** may be secured with three standard transformers, connected as shown in Fig. 40. The unit at the left has a ratio of 10 to 1, and is

Digitized by Google

connected from phase to neutral. The other two have ratios of 9 to 1, with their secondary coils in multiple, and are arranged as two limbs of a star-connection (Y), to give 220 volts across the outer wires. The three-phase system is therefore unbalanced by this arrangement, since half the energy is taken from one phase. The capacities of the transformers should be selected accordingly.

It is possible to use transformers with ratios of 10 to 1, but if this is done each of the phases supplying the right-hand transformer must be provided with a boost of 15 per cent.

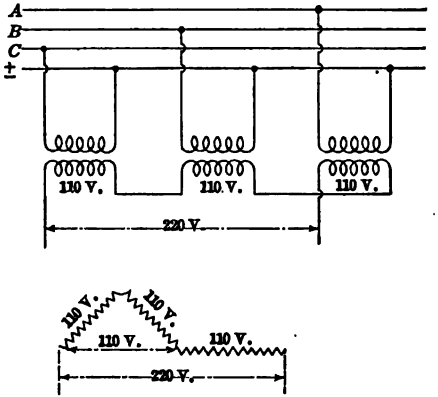

FIG. 41.—Conversion from three-phase to single-phase, with balanced load.

**128. Conversion from three-phase to single-phase.** In connection with electric welding and other work requiring single-phase energy in amounts so large that the unbalanced load is serious, the load may be equally distributed among the three phases by the scheme of connections shown in Fig. 41. Equal currents are drawn from the three phases to supply 220-volt single-phase energy. Each transformer must have capacity to carry the entire secondary single-phase current, so that the total transformer capacity must be 1.5 times the load.

## PROTECTIVE APPARATUS

**129. The insertion of fuses for protection in low-tension lighting systems** has become universal, because of the low cost of fuses as compared with circuit breakers. In power systems where the circuits are opened frequently, the circuit-breaker is found preferable.

**130. Plug-fuses.** The fire hazard from the flash which occurs at the melting of a fuse led to the development of **enclosed fuses**, the earliest of which was the Edison plug-fuse, which is used very generally on circuits up to 20 amp.

**131. Cartridge fuses.** Cartridge fuses, consisting of a tube of fibrous material in which the fuse is mounted, with a **filler** of fire-resisting powders are used largely on circuit operating at 250 to 600 volts. Cartridge fuses have been fully standardized by the National Electrical Code as to voltage and current as follows: 250-volt: 0–30 amp., 31–60 amp., 61–100 amp., 101–200 amp., and 201–500 amp.; 600-volt: 0–30 amp., 31–60 amp., 61–100 amp., and 101–200 amp.

**132. The law of the operation of fuses** was discovered by Preece in 1888. It may be stated in the form,

$$\text{Current} = a\sqrt{d^3} \qquad (6)$$

Digitized by Google

$d$ being the diameter of the wire expressed in inches. The value of the constant "$a$" varies with the kind of metal used. For copper it is 10,244; for aluminum 7,585, for lead 1,379, for tin 1,642 and for iron 3,148.

**133. Fusing Currents of Copper and Aluminum Wires**

| | Size of wire, A.W.G. | | | | | | |
|---|---|---|---|---|---|---|---|
| | 8 | 10 | 12 | 14 | 16 | 18 | 20 |
| $\sqrt{(d)^3} =$ | 0.046 | 0.0325 | 0.229 | 0.0162 | 0.0114 | 0.0081 | 0.0057 |
| Fusing current of copper (amp.) | 472 | 334 | 235 | 166 | 117 | 83 | 58 |
| Fusing current of aluminum (amp.) | 349 | 246 | 174 | 123 | 86 | 61 | 43 |

**134. The protection of a distributing system is necessarily a compromise among conflicting conditions. Location of fuses** should be such that the area affected by the operation of a fuse is as small as possible. On the other hand a fuse is prone to operate when it should not; therefore fuses should not be multiplied unnecessarily.

**135. Fuses in overhead alternating-current lines.** Where the mains are not interconnected, experience has demonstrated that very few fuses should be used. The principal branches should be provided with **disconnect-switches** which can be readily used in locating trouble, and the use of fuses should be limited to branches where there is a continuous hasard such as trees, or a very long run which is otherwise exposed. When a branch or feeder is in trouble, it is isolated by the use of disconnect-switches and all dependent branches affected are transferred to adjoining circuits through emergency disconnect-switches provided for the purpose.

**136. In underground low-tension networks,** the **sectionalizing** (with fuses) must be done with great thoroughness owing to the density of the load, the length of time required to make repairs and the importance of the service. Trouble on a distributing main should be limited to the block in which it occurs, and if lines are carried on both sides of the street, to one side of the street. It is practice to place fuses at all junction points in networks. **Sheet-copper fuses** are generally used for this purpose. The section of the copper where fusion takes place is designed to fuse at about twice its normal load.

**137. The feeders are fused at the point where they connect into the network,** to protect the network against trouble on the feeder. It is not usual to provide fuses on low-tension feeders at the station, as the operator on duty can open the switch in case it is necessary.

**138 .Fuses at subway transformers.** When the network is fed by subway transformers, an additional link is introduced in the system. Both sides of the transformer should be connected to the system through **junction boxes** so that the unit can be easily cut off from the system if it burns out.

**139. Line transformers should be provided with primary fuses** of such size that they will not blow unnecessarily. The **porcelain type** of fuse furnished with the transformer has proven very satisfactory for transformers up to 20 kw. **Aluminum is used as the fuse metal** up to 15 amp. or 20 amp, at 2,200 volts. Above 25 amp. various types of fuse have been tried, but the amount of energy concentrated at the arc makes the problem difficult. Some of these give promise of success, but practice is not at all standardized. The cartridge fuse is effective to 50 amp., but it is difficult to keep it dry enough to prevent the filler from absorbing moisture when used out of doors.

**140. Circuit-breakers** are the preferable means of protection where automatic cut-outs operate at frequent intervals, and also for circuits operating at high voltages, controlling loads of 100 kw. and upward. In general, the circuit-breaker is expensive in first cost but inexpensive in operation, while the use of fuses involves a considerable maintenance charge, but small first cost.

Digitized by Google

On low-potential circuits the circuit-breaker consists of a switch of suitable design, with which is combined a series coil so arranged that it lifts a movable core and releases a spring-actuated mechanism which opens the switch. Circuit-breakers are designed so that they may be adjusted to operate at any point between 80 per cent. and 150 per cent. of their rated capacity.

In **high-potential systems** a series transformer may be installed at a convenient point to operate the tripping-coil of the circuit-breaker. On circuits operating at pressures above 600 volts the switch is designed to break in oil.

**141. The operating mechanism of the circuit-breaker** may be controlled by hand, or electrically by means of solenoids. In **hand-operated breakers** the energy required to open the circuit is stored in springs compressed during the act of closing. In **electrically operated breakers** the power for both closing and opening the circuit is supplied through solenoids or motors.

The larger sizes of circuit-breakers and those operating at the higher voltages are usually controlled electrically, on account of the power required, and because of the greater facility of operation. Continuous current is usually available in generating stations and substations, from the exciter system, and is therefore used for the operation of solenoid-controlled breakers where possible. Motor-operated breakers are often equipped with alternating-current motors.

**142. Relays.** It is usual to design relays for operation with an **inverse time element**; that is, with a relay set to operate at 100 amp. after 10 sec., it will operate at about 300 amp. in 5 sec. and almost instantaneously at 1,000 amp. This characteristic gives prompt action in opening the line under short-circuit, while reducing the likelihood of unnecessary interruption under brief overloads.

**143. The arrangement of relays** must be such that a short-circuit between any two wires will operate the breaker. On single-phase circuits

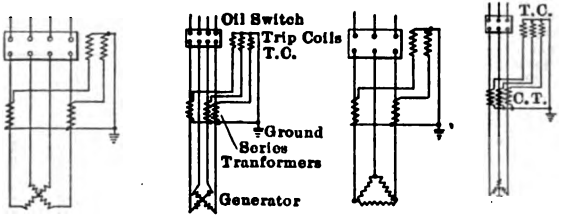

FIG. 42.—Relay arrangements for two-phase and three-phase circuits.

one relay is sufficient to accomplish this. On two-phase systems supplying lighting and motor service it is desirable to provide separate relays and circuit-breakers for each phase. In the three-phase, three-wire system without grounded neutral, relays are required in two of the three wires; the three-pole type of circuit-breaker is used. In the three-phase, four-wire system having the neutral point grounded, it is essential that relays be installed in each phase wire, with single-pole breakers; in case of a ground on one phase the corresponding circuit-breaker opens without interrupting the lighting service on the other phases (Fig. 42).

**144. Relays on three-phase transmission lines.** It is customary to provide relays at the point of supply, commonly called **overload relays**. Where several lines are operated in parallel, further protection is necessary. When the lines are connected to the same bus at each end, a short-circuit

Digitized by Google

will draw energy from both ends and circuit-breakers must be provided at both busses. The relays at the receiving end must, however, be of a type which will operate only on reversal of the flow of energy. The converting equipment is provided with reverse-power relays on the secondary side.

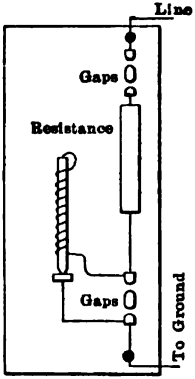

FIG. 43.—Solenoid type of lightning-arrester.

**145. Speed-limiting devices.** It is important that synchronous converters be protected by speed-limiting devices designed to operate the direct-current circuit-breaker when the speed exceeds a safe value.

**146. Lightning Protection.** Overhead distributing lines are susceptible to the effects of lightning. A discharge among the clouds causes an abrupt discharge of potential on the wires, which must be given an opportunity to escape to earth without injuring the insulation of the apparatus.

**147. The function of lightning-arresters** is to protect apparatus by passing the discharge of lightning to ground, without permitting the arc thus established to be maintained. This may be accomplished on potentials up to 600 volts by a short gap of non-arcing metal. At 2,200 volts or higher, several gaps in series are necessary, with a resistance to limit the current. Since each wire of the circuit is affected, discharge gaps must be provided between each wire and ground.

**In systems having one side grounded,** every discharge is likely to be followed by the generator current, as there is a fixed difference of potential between the circuit and earth. Arresters on grounded systems must, therefore, meet more severe requirements than those on ungrounded systems.

The problem of protection of transmission lines becomes more complex as the voltage is increased, and the study of protective methods for lines operating at 20,000 volts and upward is leading to new developments every year. The discussion in this Section will be restricted to alternating-current distributing systems operating at less than 5,000 volts.

**148. Types of Arresters.** The wide range in severity of lightning flashes makes it well-nigh impossible to design an arrester which will protect apparatus and yet withstand the effects of a direct stroke at any point nearby. The arresters described in the succeeding paragraphs (Par. **149** to **152**) include the leading commercial types which have been used in distribution work.

**149. The Garton-Daniels arrester,** Fig. 43, consists of air gaps and resistances, with a solenoid so arranged that the plunger is raised by the passage of the generator current, thus placing additional gaps in series and rapidly diminishing or stopping the flow of energy. The lightning discharge passes across the shunted gaps to ground owing to the inductance of the solenoid.

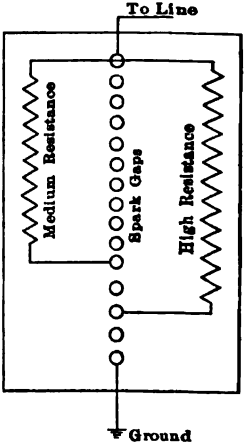

FIG. 44.—Multi-gap lightning-arrester.

**150. Multi-gap arrester.** A modification of the spark-gap and resistance type of arrester has been employed quite extensively. This is illustrated in Fig. 44, as made for 2,300 volts, and consists of three paths of discharge, one of which has a high resistance (100,000 ohms), another a resistance of about 300 ohms, and a third which consists of 13 or 14 gaps without resistance. The impedance

Digitized by Google

of the unit is such that discharges of very high frequency pass over the 13 gaps, while those of lower frequency pass over the smaller number of gaps through one of the resistances. A slightly modified form is shown in Fig. 45.

**151. The aluminum-cell arrester** has given good results because of its ability to stop the flow of current promptly and safely. It has been found especially valuable at transmission voltages where its expense is justified by the importance of the service. It is not suited for outdoor distribution work, since it requires daily charging and supervision and cannot be left continuously in circuit.

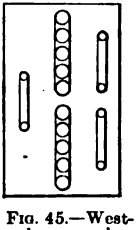

FIG. 45.—Westinghouse low equivalent arrester.

**152. The compression type of arrester,** Fig. 46, consists of a series resistance with air-gaps, assembled inside of a porcelain tube, the top of which is capped and sealed. The air-gaps are surrounded by a grounded strip of iron outside of the tube, which acts as a means of equalizing the potential gradient. The discharge of the arrester expands the air and compresses it, since the tube is sealed; hence the name compression type. This arrester, having but one path to ground, is of limited capacity.

**153. Location of arresters.** All of the above-described types of arresters are in general use on distributing systems in America, and each gives reasonably good protection to apparatus when placed in its immediate vicinity. Experience has fully demonstrated that lightning discharges do not travel any great distance along a line, owing to the very high frequencies of this form of energy. The arrester must, then, be located as near the apparatus as practicable, and preferably on the same pole. Complete protection of distributing transformers would require that an arrester be placed on every transformer pole.

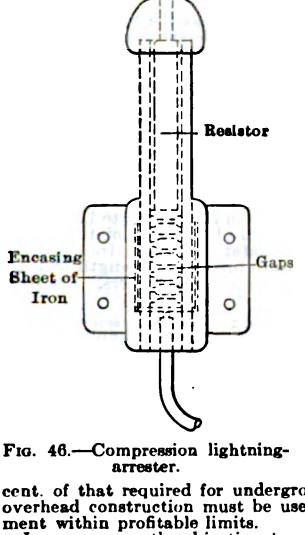

FIG. 46.—Compression lightning-arrester.

The experience of large companies, however, has been that the cost of the damage to apparatus from lightning is not as large as the fixed charges on the arrester equipment, when complete protection is provided. The exact point at which these two elements of cost become a minimum varies with the value and the size of the transformers, since it costs as much to protect a 1-kw. unit as a 50-kw. unit. Practice has not yet become standardized, as the subject is still being studied and reliable conclusions can be reached only after a number of years' further experience.

**154. The use of lightning-arresters on transformer poles** has been found to materially diminish the number of interruptions of service due to blowing of transformer fuses, and this tends to make the more liberal use of arresters desirable.

## OVERHEAD CONSTRUCTION

**155. General.** Overhead construction is an economic necessity in a large part of every city. The **investment** for overhead lines in outlying districts usually is from 15 per cent. to 30 per cent. of that required for underground construction, and it is obvious that overhead construction must be used wherever feasible, to keep the investment within profitable limits.

In many cases the objection to overhead lines is minimized by locating them in alleys.

Digitized by Google

**156. Poles.** Distribution lines are necessarily carried on wooden poles. Iron poles are objectionable on account of the risk to linemen in handling "live" primary circuits. Iron poles are used in some cases for street-lighting circuits which are so operated that it is not necessary to do any work on them while they are "alive." The cost of iron poles is about twice that of wooden poles.

**157. Concrete poles** are being used increasingly in sections where the ravages of insects and the nature of the soil make the life of wooden poles very short. They are also being introduced for transmission work in places where iron poles would otherwise be required.

**158. The woods which are best suited for pole work** are Michigan cedar, Western cedar, chestnut, pine, and cypress.

**159. The Michigan cedar** grows with a natural **taper** of about 1 in. in diameter to every 5 ft. or 6 ft. of length, making a very substantial and rigid pole.

**160. The Western cedar,** which grows in Idaho and Oregon, **has a** natural **taper** of about 1 in. in 8 ft. to 10 ft. of length. For the same size of top the diameter of the butt is, therefore, smaller than that of the Michigan cedar. The surface of Western cedar is smoother than that of the Michigan cedar and the poles are very straight and neat in appearance. It is necessary on important lines to use nothing smaller than 8-in. tops with these poles, in order to secure adequate diameter at the ground line.

**161. The chestnut pole** is quite different from the cedar poles. The specific gravity of the wood is high and the surface is irregular and knotted, making the appearance of the chestnut pole not as good as that of cedar.

**162. Pine and cypress poles** are more like cedar in their general characteristics of weight and strength. Their use is limited to sections of the country where the timber is native, as their life is comparatively short.

**163. On the Pacific coast, California redwood** and some other native woods are used very generally.

**164. Pole stresses.** The stress acting on a pole at the top causes a tension in the fibre of the wood on one side of the pole and a compression on the opposite side. For a round pole the maximum fibre stress is:

$$f = \frac{384\,PL}{3.14\,(d)^3} \qquad \text{(lb. per sq. in.)} \qquad (7)$$

in which $P$ is the pull at right angles, in pounds, at the distance $L$ ft. above ground, and $d$ is the diameter at the ground line, in inches. Expressed in another form, Eq. 7 becomes,

$$d = \sqrt[3]{\frac{384PL}{3.14f}} \qquad \text{(in.)} \qquad (8)$$

The unit stress $f$ should be taken at not more than 10 per cent. to 12 per cent. of the ultimate breaking strength, as determined by tests of the timber in the form of poles; that is, the **factor of safety** should be from 8 to 10. Cedar, redwood and pine have an **ultimate breaking strength** of about 7,000 lb. per sq. in. when tested in the form of large timbers. Chestnut is slightly stronger, having a strength of 8,000 lb. per sq. in.

**165. Example of calculation of pole diameter.** If a self-sustaining (unguyed) pole is to support a line which exerts a horizontal pull of 800 lb. at a height of 30 ft. above the ground, what should be its diameter at the ground line to safely carry the load?

$f = \frac{1}{10}$ of $7{,}000 = 700$; $P = 800$, $L = 30$ ft.

$$d = \sqrt[3]{\frac{384 \times 800 \times 30}{3.14 \times 700}} = \sqrt[3]{4{,}193} = 16.1 \text{ in.}$$

This would call for the use of a 35-ft. pole with a butt-diameter of 16 in. at the ground line. The top-diameter of a Michigan cedar pole of this size would be from 8 in. to 9 in. In city practice where turns are made at right angles, which cannot be supported by a guy, the use of such poles is often necessary.

**166. Wind pressure.** The design of pole lines to withstand wind pres-

Digitized by Google

sure must be considered where they are exposed, though the average pole-line distribution is so protected by buildings and trees that it is not subject to the full force of windstorms. The wind pressure on a normal flat surface is

$$p = 0.004\ V^2 \qquad \text{(lb. per sq. ft.)} \qquad (9)$$

where $V$ is the velocity in miles per hr.; if Weather-Bureau observed velocities are used, they should be corrected.* Thus $p = 40$ lb. per sq. ft. at 100 miles per hr., 22.5 lb. at 75 miles, 10 lb. at 50 miles, and 2.5 lb. at 25 miles. The pressure on a cylindrical surface whose axis is normal to the wind is one-half that on a plane surface equal in area to the projected area of the cylinder. Thus for round smooth wires:

$$p = 0.002\ V^2 \qquad \text{(lb. per sq. ft.)} \qquad (10)$$

For bare concentric strands H. W. Buck† found that the constant in Eq. 10 is 0.0025.

The wind pressure on a 40-ft. pole, of which 34 ft. is above ground, with 7-in. top and 14-in. butt, would be calculated as follows. Projected area = $\{(7+14)/2\} \times 34 \times 12 = 4{,}284$ sq. in. = 29.75 sq. ft. Assuming a wind velocity of 60 miles per hr., $p = 0.002 \times (60)^2 = 7.2$ lb. per sq. ft. Total pressure on pole = $29.75 \times 7.2 = 214$ lb. This force acts at the centre of gravity of the projected area, which is a long narrow trapezoid; or 15.1 ft. from the ground-line. The moment of this force about the ground-line is therefore $214 \times 15.1 = 3{,}230$ lb-ft. Taking the diameter of No. 6 A.W.G. triple-braid weather-proof wire as 0.32 in., the total wind pressure at 60 miles per hr., on a 120-ft. span, would be 23 lb. and on twenty wires it would be 460 lb.; this resultant force would act at a point about 3 ft. below the top of the pole, or 31 ft. from the ground-line. The resulting moment would be 14,260 lb-ft. The sum of the wind pressures on pole and wires would be $3{,}230 + 14{,}260 = 17{,}490$ lb-ft. A rough-and-ready rule is sometimes used that the wind pressure on the pole itself is about equal to that on five No. 6 A.W.G. weather-proof wires.

High wind velocities are attained at times in nearly all parts of North America, and it is advisable, therefore, to provide pole braces or guys on exposed lines.

**167. Selection of poles.** It is usual to select poles with 7-in. tops for important distributing lines.

The **height** of the poles selected for distribution purposes must be governed by the clearance over local obstructions and also by the number of cross-arms to be carried on the poles. Clearance over trees is especially troublesome in residence sections where trimming will not be permitted. In general it is desirable to use poles not less than 30 ft. long where primary lines are carried, and in built-up sections a minimum size of 35 ft. is preferable.

**168. Poles for joint-line construction.** Where joint-line construction with standard cross-arms is used, it is not usually possible to employ poles shorter than 35 ft. In a few cases the lines have been placed in cable and carried on 25-ft. poles on rear-lot lines. The use of poles over 40 ft. long is to be avoided wherever possible, on account of the cost, the increased danger in storms and the difficulty of handling transformers and service connections.

**169. Poles should be spaced** in approximately equal span lengths of about 100 ft. to 125 ft., to keep the sag within safe limits and to provide a sufficient number of points at which service drops may be taken off. The spans near self-supporting corner poles should be about 75 ft. long in order to relieve the strain on the corner pole. **The poles should be placed** opposite lot-lines to avoid interference with the rights of abutting-property owners.

**170. Shaving and painting.** It is considered good policy to carefully shave all poles, trim the knots, and give them two coats of paint. A dark green color is very commonly used because of its harmony with foliage in residence districts.

Digitized by Google

**171. Stepping.** Transformer poles and others which are climbed at frequent intervals should be provided with pole steps. It is the practice in many of the large city systems to provide steps on all poles.

**172. Gaining.** The gains should be cut for the cross-arms before the poles are erected. The **distance between cross-arm centres** must be sufficient to give clearance for service drops and allow a safe working space for linemen. The space usually allowed is about 24 in.

**173. Pole setting.** Experience has proven that the following practice is conservative, as regards the depth of setting.

| Size pole (ft.) | 30 | 35 | 40 | 45 | 50 | 55 | 60 | 70 |
|---|---|---|---|---|---|---|---|---|
| Depth (ft.) | 5 | 5.5 | 6 | 6.5 | 6.5 | 7 | 7 | 7.5 |

Corner poles should be set about 6 in. deeper than the above. In rocky soil where boulders may be tamped about the poles, they need not be set as deep.

The poles should be placed so as to bring their natural curvature into the plane of the line. At corners a slight **rake** may be given in a direction opposite to the pull of the load. Several tampers should be employed to one shoveler, in **back-filling**, in order to insure the stability of the pole. Water may be used to advantage, where available, in settling the back-fill. In swampy soil, the digging of holes is greatly facilitated by the use of a **sand-barrel**. This consists of a sheet-iron cylinder about 30 in. in diameter and 3 ft. long, which is separable into two parts lengthwise, and is readily removed after the pole is in place. Various methods of setting are shown in Fig. 47.

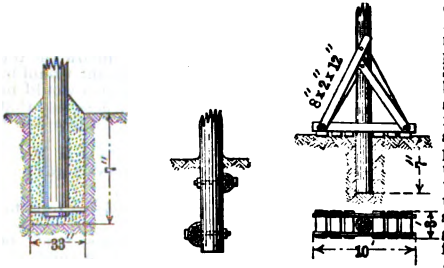

FIG. 47.—Methods of setting self-sustained poles.

**174. Guying and bracing.** Where the direction of a line changes, the tension of the wire should be supported by guying or bracing. The bracing method requires considerable space, and is more unsightly than a guy. Guys are secured in various ways, depending upon the space and the clearance required. Where nothing prevents, the guy cable may be secured to an **anchor** of timber or some form of patent anchor (Fig. 48). On public thoroughfares guys cannot be run directly to anchors without interfering with traffic, and the guys must be run to **stubs** at such height as to permit free passage of traffic beneath. Guys over roadways should clear about 25 ft., and those over pathways about 12 ft. (Fig. 48).

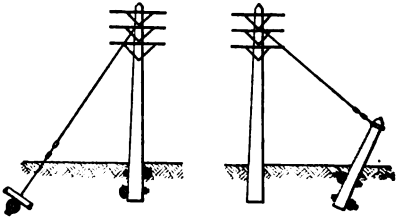

FIG. 48.—Anchor and stub guy.

Where side-arm construction is used it is necessary at corners to guy the cross-arms as well as the poles. At heavy corners a "head" guy is run from the base of the corner pole to the upper part of the next pole in the line.

Digitized by Google

The tension in the corner spans may thus be reduced, relieving the strain on the corner pole. In straight-away lines the head guy is used to limit the extent of damage in case several poles go down; this is sometimes called "storm guying."

**175. Galvanized steel cable is generally employed for guying purposes** because of its high tensile strength. Such cable is made in sizes varying in diameter by steps of $\frac{1}{16}$-in., from $\frac{1}{4}$-in. up. The **ultimate breaking strength of $\frac{1}{4}$-in. cable** is about 3,000 lb.; $\frac{5}{16}$-in., 4,500 lb.; $\frac{3}{8}$-in., 6,000 lb.; and $\frac{1}{2}$-in., 12,000 lb. Having calculated the tension, the size of guy cables should be such that the strain will be from one-fourth to one-fifth the ultimate breaking strength of the cable, or the **factor of safety of the steel cable**, from 4 to 5. Anchors should be placed at a distance from the pole not less than one-quarter the height of the guy attachment. In general, $\frac{1}{4}$-in. cable is used for the smaller loads, while the $\frac{3}{8}$-in. size is standard for corner poles where the load of the ordinary two-arm to three-arm distribution line is to be supported.

**176. Strain insulators.** It is important that guy cables attached to stubs be equipped with strain insulators not less than 8 ft. from the ground. This precaution is advisable for the protection of the public and of linemen.

**177. Cross-arms. Southern pine** and **Oregon fir** are the best woods for cross-arms because of their straight grain, high tensile strength, and durability. The **cross-section** should be such that the arm will safely bear

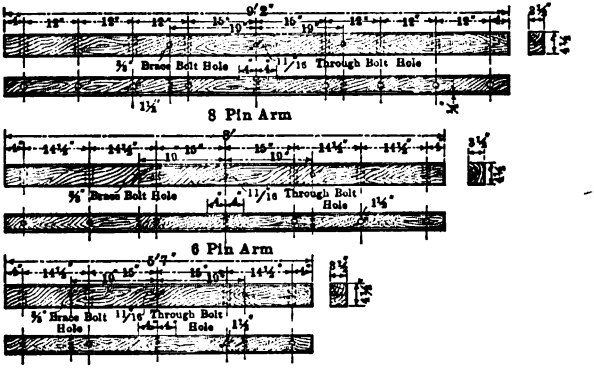

FIG. 49.—Dimensions of standard cross-arms.

the weight of a lineman in addition to that of the wires. Experience indicates that a cross-section 3.5 in. wide by 4.5 in. high is ample for the average requirements of distributing lines. For transformers of 20 kw. and larger it is usual to provide arms of a larger cross-section. Main lines are commonly built of six-pin arms, with four-pin arms on the smaller distributing lines. Where secondaries for both lighting and motor service must be carried on the same arm, it is usually necessary to employ six-pin arms.

The **spacing of pins** should provide safe working room for linemen and should take into account the average sag of the wires. Under the usual working conditions of distributing lines, it is not safe to attempt to use spacings less than 12 in. The spacing of the pole pins must give sufficient room for the men to climb to the upper arms, at least 30 in. being required for safety. The dimensions and spacings of standard cross-arms are shown in Fig. 49.

**178. Double cross-arms.** At corners, terminals, and other points where any unusual load is to be supported, the poles should be fitted with double arms. In turning corners on a single pole, the double-arming of

Digitized by Google

both sets of arms makes the pole difficult of access to linemen. It is preferable, in case there are more than two cross-arms, to double-arm the first pole away from the corner in each direction, as shown in Fig. 50.

**179. Cross-arm fittings.** Cross-arms are fastened to the pole by **through-bolts** which should be ½ in. in diameter and from 12 in. to 16 in. long. The side on which the arm is attached is known as the **face of the pole. Cross-arm braces** are usually made of strap iron about ¼ in. by 1 in. and 26 in. to 30 in. long, and are attached to the pole by means of lag screws and to the cross-arms by stove bolts. For **side-arms** it is usual to use a brace of angle iron. This is rigid enough to bear the weight of a lineman on the step.

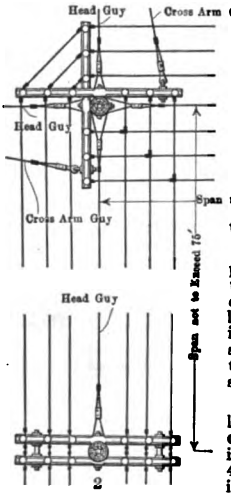

FIG. 50.—Reinforcement of corner poles by double cross-arms on adjacent poles.

**180. Cross-arm pins. Wooden pins** are preferred for distribution work on account of their low cost and insulating qualities. Locust, elm, oak and some other woods are common, but locust is superior to all in strength and durability. **Iron pins** are commonly used for transmission lines where the size of the insulator necessitates a pin so long that wooden pins are not strong enough unless made undesirably large.

**181. Insulators.** The common type of insulator for distributing lines is that known as the **deep-groove double-petticoat** insulator, shown in Fig. 51. The dimensions are sufficient to carry 4,000-volt circuits safely. The point of support is low and the side strain on the pin is a minimum. These insulators are made in glass and porcelain. The glass insulator is slightly less expensive than the porcelain in the deep-groove double-petticoat type, as is most commonly used. Some companies are using porcelain for primary wires and glass for secondaries, as a means of assisting linemen in the identification of circuits. Other porcelain types for higher voltages are also shown in Fig. 51.

**182. Wire stringing.** In erecting wire, the **tension** should be made sufficient to prevent too much sag in the spans, and yet not so great as to unduly

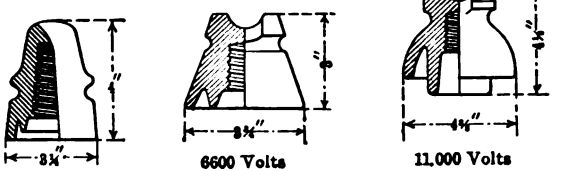

FIG. 51.—Standard types of insulators.

stress the wire. For practical purposes the approximate formula for sag and tension given by Rankine may be used:

$$T = \frac{L^2 w}{8S} \quad \text{(lb.)} \qquad (11)$$

Digitized by Google

in which $T$ is the tension in pounds, $L$ is the span length in feet, $w$ is the weight per foot of conductor and $S$ is the sag in feet at the centre of a horizontal span. If the span length is doubled, the tension must be quadrupled in order to keep the sag the same. If the tension is the same on several spans of different lengths, the sag is different in each span. The sag of any span when the tension is known is found by changing Eq. 11 to the form, $s = L^2w/8T$.

**183. The maximum tension in a span** is limited by the strength of the wire and supports. The **ultimate breaking strength of annealed copper wire** is about 34,000 lb. per sq. in., but the working stress should not be over one-fourth of this. The **ultimate tensile strength of hard-drawn wire** is about 60,000 lb. per sq. in. Such wire is left in the hardened condition in which it comes from the wire-drawing dies, which gives it greater strength and stiffness. The hard-drawn wire, however, should not be scratched in handling, as any injury to the surface increases the likelihood of fracture. If it is heated for soldering, its strength is reduced. Hard-drawn wire, therefore, is not adapted to general distribution work where taps must be made with soldered connections at frequent intervals, but for transmission lines and series-arc circuits it has advantages which are generally recognised.

**184. The sag and tension** of weather-proof, annealed wire and bare, hard-drawn wire may be readily determined from the tables in Par. **185** and Par. **186**.

**185. Sag Table for Weather-proof Annealed Copper Wire**

| Size A.W.G. | 10 | 8 | 6 | 4 | 2 | 1 | 0 | 2/0 | 3/0 | 4/0 |
|---|---|---|---|---|---|---|---|---|---|---|
| Tension at 1 ft. sag (lb.) | 62 | 92 | 140 | 204 | 318 | 390 | 486 | 607 | 767 | 942 |
| Sag at 100 lb. tension (ft.) | 0.62 | 0.92 | 1.40 | 2.04 | 3.18 | 3.9 | 4.86 | 6.07 | 7.67 | 9.42 |
| Weight of wire, lb. per 1,000 ft. | 50 | 74 | 112 | 163 | 254 | 312 | 388 | 486 | 614 | 754 |
| Breaking stress (lb.) | 283 | 440 | 700 | 1114 | 1772 | 2234 | 2818 | 3553 | 4480 | 5650 |

**186. Sag Table for Bare Hard-drawn Copper Wire**

| Size A.W.G. | 10 | 8 | 6 | 4 | 2 | 1 | 0 | 2/0 | 3/0 | 4/0 |
|---|---|---|---|---|---|---|---|---|---|---|
| Tension at 1 ft. sag (lb.) | 39.3 | 62 | 99 | 157 | 161 | 202 | 400 | 505 | 636 | 800 |
| Sag at 100 lb. tension (ft.) | 0.393 | 0.62 | 0.99 | 1.57 | 1.61 | 2.02 | 4.0 | 5.05 | 6.36 | 7.80 |
| Weight of wire, lb. per 1,000 ft. | 31.4 | 50 | 79.5 | 126 | 201 | 253 | 320 | 403 | 508 | 640 |
| Breaking stress (lb.) | 500 | 775 | 1240 | 1960 | 3120 | 3743 | 4560 | 5271 | 6590 | 8310 |

**187. Use of sag tables.** The tension at any other sag, or the sag at any other tension, or the sag or tension in any other length of span, may be readily found from the Tables (Par. **185** and **186**) as follows:

The tension at any other sag is $T' = T/S$, in which $S$ is the sag in feet at which the tension is desired and $T$ is the value at 1-ft. sag in the table. For example, the tension in a 100-ft. span of No. 0 weather-proof wire at a deflection of 2 ft. is

$$T' = \frac{T}{S} = \frac{486}{2} = 243 \text{ lb.}$$

Similarly, the sag at any other tension is $S' = S \times 100/T$, in which $T$ is the assumed tension and $S$ is the value of sag at 100 lb. tension in the table. For example, with No. 0 weather-proof wire the sag at 300 lb. is

$$S' = \frac{S \times 100}{T} = \frac{4.86 \times 100}{300} = 1.62 \text{ ft.}$$

For spans of other lengths, the sag or tension varies in proportion to the square of the length of the assumed span. That is,

$$S' = \left(\frac{L'}{100}\right)^2 S, \text{ and } T' = \left(\frac{L'}{100}\right)^2 T. \qquad (12)$$

Digitized by Google

For example, with No. 4/0 bare wire the tension with a span of 150 ft., at 1-ft. sag, would be

$$T' = \left(\frac{150}{100}\right)^2 \times 800 = 1{,}800 \text{ lb.}$$

Or if the tension of the line were 100 lb. in all the spans, the sag in a 150-ft. span would be

$$S' = \left(\frac{150}{100}\right)^2 \times 8 = 18 \text{ ft.}$$

**188. Expansion and contraction of spans with temperature changes.** The changes in sag due to expansion and contraction under varying temperatures are of much importance in the erection of the conductors. Lines erected during the winter months are likely to be too slack during the summer, and allowance should be made accordingly. The length of wire in a span, disregarding the elastic stretching due to the load, varies in proportion to the coefficient of expansion and the range of temperature:

$$L_t = L_o(1 + \alpha_o t) \tag{13}$$

in which $\alpha$ is the coefficient of expansion, $t$ is the temperature in deg. fahr. and $L_o$ is the length of wire at zero temperature. When the length $L_{t1}$ is known at some other temperature $t_1$, the formula becomes

$$L_t = L_{t1}\left(\frac{1 + \alpha_o t}{1 + \alpha_o t_1}\right) \tag{14}$$

The linear coefficient of expansion of copper is 0.000017 per deg. cent. or 0.0000094 per deg. fahr. P. H. Thomas has worked out a graphical solution* of sag problems which is very useful where accurate results, with considerable variation of temperature and load, are required.

In practice the pole supports have a certain degree of flexibility which tends to take up part of the slack caused by expansion and to prevent excessive strains being placed on the wires by contraction during cold weather.

**189. Table of sags recommended by National Electric Light Association.** The following table, adopted by the N. E. L. A., represents good practice in wire-stringing at various temperatures, the deflection at the centre of the (horizontal) span being given in inches.

**190. Table of Standard Sags Recommended by the National Electric Light Association**

Deflection (sag) in inches

| Span in feet | Temperature in deg. fahr. | | | | | | |
|---|---|---|---|---|---|---|---|
| | 30 | 40 | 50 | 60 | 70 | 80 | 90 |
| 50 | 8 | 9 | 9 | 10 | 11 | 11 | 12 |
| 60 | 10 | 11 | 11 | 12 | 13 | 14 | 14 |
| 70 | 11 | 12 | 13 | 14 | 15 | 16 | 17 |
| 80 | 13 | 14 | 15 | 16 | 17 | 18 | 19 |
| 90 | 14 | 16 | 17 | 18 | 19 | 20 | 21 |
| 100 | 16 | 17 | 19 | 20 | 21 | 23 | 24 |
| 110 | 18 | 19 | 21 | 22 | 24 | 25 | 26 |
| 120 | 19 | 21 | 23 | 24 | 26 | 27 | 28 |
| 130 | 22 | 24 | 26 | 28 | 30 | 32 | 33 |

**191. Transformer installations.** Transformers are usually supported on cross-arms by means of iron hangers. This class of construction is suitable for transformers of capacities up to 20 kw. For larger units the cross-arms should be double, and heavier than the standard arm. Large transformers which cannot be placed inside the building are often installed on a platform between two poles.

**192. Grounded secondaries.** To protect life and property in case a primary circuit becomes crossed with a secondary, it is very important

* Thomas, P. H. "Sag Calculations for Suspended Wires;" *Trans.* Amer. Inst. of Elec. Eng.; Vol. XXX, 1911; p. 2229.

Digitized by Google

that the secondary be grounded. This is preferably done by connecting the secondary circuit to **water pipes** where these are accessible. Where the ground must be made outdoors, the most practicable method is to drive a galvanized **iron pipe** into the ground to a depth of about 8 ft. The points to be grounded in various kinds of secondary mains are indicated in Fig. 52.

**193. The grounding of secondaries up to 150 volts has been required by the National Electrical Code** since 1913. There is some doubt as to the advisability of grounding secondaries when the difference of potential between any wire and ground is higher than 250 volts, owing to the possibility that shocks from such a system may prove fatal.

**194. When the ground connection is made to a pipe at the pole,** the ground-wire is preferably brought down the pole in half-round wooden moulding. The ground-wire may be soldered to the pipe about a foot above the ground, or may be attached by means of a pipe cap as shown in Fig. 53.

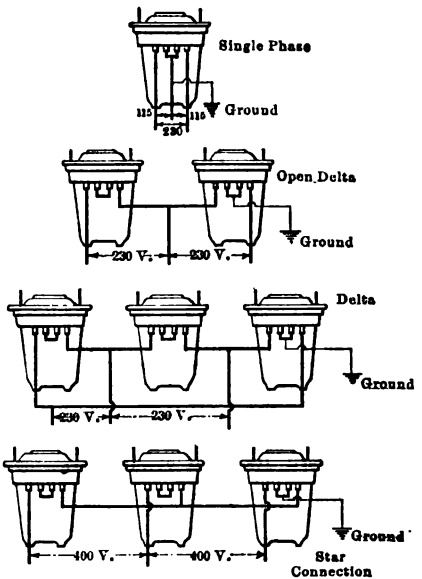

FIG. 52.—Connections for grounded secondary.

**195. Arrangement of wires.** The position of wires on the cross-arms should be assigned according to a systematic plan. Circuits should be kept on the same pins throughout their course, to facilitate maintenance work. In general, through lines should be carried on the upper arms and local distributing lines at the bottom. All the wires of a circuit should be carried on adjacent pins. Connections carried across the pole for transformers or service drops should leave one side of the pole free for climbing.

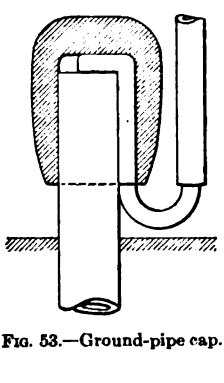

FIG. 53.—Ground-pipe cap.

**196. Joint occupancy of pole lines.** The use of a joint line of poles is preferable to separate lines, on thoroughfares where there are many service drops, as it avoids much confusion. Where poles are occupied jointly by both electric-light and telephone companies, *the lighting wires should always occupy the upper position.* A clearance of about 4 ft. should be maintained between the lower lighting wires and the telephone wires. Joint-line construction is the rule in most of the larger cities. For details of recommended forms of joint-line construction, see the "Report of Committee on Overhead Line Construction," *Trans.* N. E. L. A., 1911.

Digitized by Google

## UNDERGROUND CONSTRUCTION

**197. Edison tube system.** The underground system devised by Edison consisted of 20-ft. lengths of iron pipe inside of which were copper rods imbedded in compound to exclude moisture. These lengths were made with various sizes of conductor from No. 4 A.W.G. up to 500,000 cir. mils for mains and up to 1,000,000 cir. mils for feeders. Feeder tubes were provided with three pressure wires to indicate at the station the pressure at the end of the feeder.

**198. Arrangement of Edison tube system.** Edison tube is joined by stranded connectors enclosed in cast-iron couplings which are filled with hot compound. At intersections the tubes are interconnected through fused junction boxes. Such tube lines are carried along each side of the street near the curb except where consumers are scattered or where an alley is used. The Edison tube system was the standard method of distributing low-tension energy underground until about the year 1897. The change to cable was made on account of the inability of the tube feeders to carry overloads without causing burn-outs. The necessity of opening street pavements in each case where repairs were made, also involved considerable expense.

**199. Conduit systems.** The early alternating-current and series-arc systems which were installed underground were unable to use a system similar to the Edison tubes because of the higher voltages employed. They were compelled to devise a drawn-in conduit system with manholes for handling the cables. Creosoted wooden pump log was tried and was satisfactory for some classes of work, but was too short-lived and inflammable.

Other systems were devised in which the ducts were intended to provide insulation, but experience proved that it was not practicable to maintain such a system. This led to the development of methods in which the insulation was applied to the conductor and the conduit was of some durable fire-proof material.

**200. Modern standard conduit systems.** Various forms of duct were tried out, but the most suitable were found to be those of fire-proof material such as terra cotta and clay tile.

A conduit made entirely of concrete and known as **stone pipe** has been used to some extent instead of clay tile. This is made in 5-ft. lengths and jointed with metal ferrules to preserve the alignment, single duct only being used. The conduit is laid in concrete, making a solid and durable duct system. The concrete pipe is fragile, however, and the breakage is likely to be greater than with the tile duct, if not carefully handled.

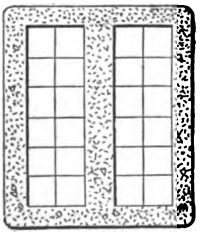

FIG. 54.—Arrangement of ducts for a large line.

Various forms of **fibre conduit** have also been used to some extent. These are laid with concrete around and between them, so that if the fibre disintegrates in after years there will remain a concrete duct system. The principal advantage is in the ease of handling and lack of breakage.

**201. Laying out a conduit line.** In the design of a draw-in duct system, the number of ducts, the size of manholes and their location are the important considerations. The number of ducts must be sufficient to care for the local distribution, for feeders, for transmission lines and for future requirements. It is desirable to lay sufficient reserve ducts to care for probable requirements for about 5 years ahead.

The **maximum number of ducts** which it is advisable to put into a line is governed chiefly by the safety of the cable equipment. The space available for training the cables is limited, and if more than twenty to twenty-five cables are carried through a manhole, a large part of the load is endangered by a failure of any of the cables. Where conditions are such that a very large line must be used, protection may be had by separating one-half of the duct line from the other by a 6-in. concrete barrier and by building double manholes. A line having more than four ducts in each layer is to be avoided where possible on account of the difficulty of properly training the cables. The arrangement shown in Fig. 54 is a desirable one where twelve or more ducts are laid.

Digitized by Google

**202. Manholes.** Manholes must be provided in sufficient number to permit the drawing in of cable without overstraining the insulation. Thus the **manhole spacing** should be not over 500 ft., with large cables 400 ft. is a safer limit. Where distribution by overhead lines in alleys with underground lines on the street is used, manholes should be put opposite alley intersections as far as possible. The number of manholes required where numerous underground service connections are needed must usually be sufficient to enable services to be brought in at intervals of 25 ft. to 100 ft. In distribution by means of subway-type transformers and a secondary network, it is usually necessary to build extra large manholes for the transformers in order to get sufficient room and proper ventilation.

Manholes should be so designed that the cables may be trained with a minimum of waste and with sufficient space to enable a jointer to work efficiently, as in the oval-shaped manhole shown in Fig. 55. At intersections a square design is preferable, as shown in Fig. 56. In practice it is usual to provide manholes 5 ft. by 5 ft. at **junctions** where there are eight ducts, that is, where two four-duct lines cross; 6 ft. by 6 ft. where there are twelve to eighteen ducts; 7 ft. by 7 ft. where there are twenty or more, and larger as the needs of the case may require.

**The size and the shape of manholes** are often governed by local obstructions such as gas or water pipes, or conduit lines of other companies. The depth must be sufficient to give head room, and yet should not be so great as to carry the floor of the manhole below the sewer level. Service manholes may be 5 ft. high inside but junction manholes should be 6 or 7 ft. from roof to floor. In some cases a shallow form of manhole known as a **handhole** is used for distribution laterals. These are made about 3 ft. by 4 ft., and 4 ft. deep. They are placed above the conduit line so that only the top row of ducts enters the handhole. The distributing mains are thus accessible for service taps, and the through lines in the lower ducts are not in the way.

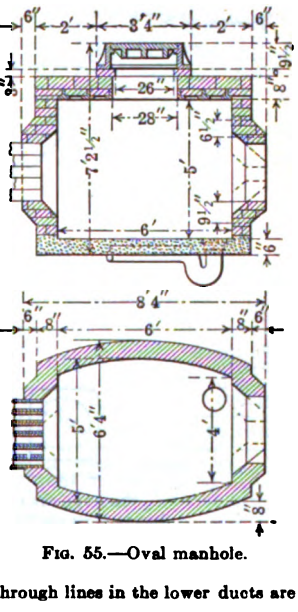

FIG. 55.—Oval manhole.

**203. Forms of duct.** Tile conduit is made in single- and multiple-duct pieces, single-duct pieces being about 18 in. in length, and multiple-duct 36 in. long. The dimensions of ducts in general use are shown in Fig. 57. Multiple-duct is somewhat cheaper than an equal number of single ducts and requires less labor. In a large system it is considered preferable to use single-duct to secure the advantage of having two thicknesses of tile between adjacent ducts. The single-duct also has the further advantage that the joints may be staggered, thus making it less likely that the heat of a burn-out may damage the cables in adjoining ducts.

**204. Installation of conduit system.** In laying a line of ducts the grades must be carefully established so that no pockets are formed where standing water may freeze and injure the insulation of the cables and break the tile. It is important that manholes where work must be done frequently, or where transformers or junction boxes are installed, be provided with sewer connections. The conduit line is protected from future excavators, and made secure against the possibility of getting out of alignment, by surrounding it with 3 in. of concrete on all sides. The con-

crete further acts as a water shed and minimizes the leakage of gas into the conduit system.

**Manholes are constructed with** brick walls and concrete floor and roof. Concrete walls may be used where there are no pipes to interfere with the use of the forms. The brick should be sewer brick, laid up with a good cement mortar, with an 8-in. wall. The roof must have sufficient strength to support the heaviest street traffic and its design, therefore, varies with the size and shape of the manhole. **Manhole covers** are made of cast iron, the upper surface of the cover being roughened or scored to prevent accidents to teams or pedestrians. It is desirable to provide openings in the covers for purposes of ventilation.

**205. Cost of fifteen-duct line.** The items of cost in constructing a fifteen-duct line as given by W. P. Hancock* are as follows:

| | Per duct-foot | |
|---|---|---|
| Lumber at $15.00 per M ft. | $0.0105 | |
| Concrete at $4.85 per yd. | 0.0231 | |
| Mortar at $3.98 per yd. | 0.0026 | |
| Tile at $0.05 per ft. | 0.0502 | |
| Total material. | | $0.0864 |
| Excavation and filling at 15 cents per hr. | 0.0266 | |
| Placing lumber at 20 cents per hr. | 0.0004 | |
| Placing concrete at 15 cents per hr. | 0.0029 | |
| Placing mortar at 25 cents per hr. | 0.0016 | |
| Laying tile at 50 cents per hr. | 0.0040 | |
| Hauling away dirt at 50 cents per hr. | 0.0047 | |
| Total labor. | | 0.0402 |
| Inspection, 50 cents per hr. | | 0.0033 |
| Engineering expenses. | | 0.0214 |
| Incidentals, 5 per cent. | | 0.0116 |
| Grand total per duct-ft. | | $0.1629 |

**206. Cost per duct-foot for duct-lines of various sizes.** The cost per duct-foot of various sizes of duct-lines without manholes, at various costs of paving per sq. yd., as given by Hancock,* are as follows (Par. **207**):

**207. Table of Costs of Duct-lines per Duct-foot**
Cents per Duct-foot

| No. of ducts | Cost of repaving per square yard | | | | | | |
|---|---|---|---|---|---|---|---|
| | None | $0.50 | $1.00 | $1.50 | $2.00 | $3.00 | $3.50 |
| 2 | 24 | 29 | 34 | 38 | 43 | 52 | 56 |
| 4 | 22 | 25 | 27 | 30 | 33 | 38 | 41 |
| 6 | 20 | 22 | 24 | 26 | 28 | 32 | 34 |
| 9 | 19 | 21 | 22 | 24 | 25 | 28 | 30 |
| 12 | 19 | 20 | 21 | 23 | 24 | 26 | 28 |
| 16 | 18 | 19 | 20 | 21 | 22 | 24 | 25 |
| 20 | 17 | 18 | 19 | 20 | 21 | 22 | 23 |
| 24 | 17 | 18 | 18 | 19 | 20 | 21 | 22 |
| 30 | 16 | 17 | 17 | 18 | 19 | 20 | 21 |
| 40 | 16 | 17 | 17 | 18 | 18 | 19 | 20 |
| 50 | 16 | 16 | 17 | 17 | 18 | 19 | 19 |

**208. Cost of manholes.** The costs of certain sizes of manholes as built under conditions existing in the City of Chicago are given in the following table, in Par. **209**. The cost of paving is not included. The dimensions are those inside the manhole, the last being depth.

**210. Types of cables.** Cables for underground electric light and power circuits are made up in single, duplex, concentric, triplex, etc. Duplex and triplex cables are those in which two conductors are enclosed in one lead sheath side by side, while concentric cable is made up with the conductors concentrically disposed.

In general, single-conductor cable is used when frequent taps are required, as in distributing mains, while multiple-conductor cables are used for through lines. Duplex cable has been used quite extensively in series-arc systems. It is difficult to train, and susceptible injury from bending at too small a radius. Duplex and triplex cables are somewhat less expensive than their equivalent in single-conductor cables with the same insulation.

The concentric arrangement is employed for large low-tension feeders in some cases. This arrangement is advantageous as it permits the use of a single duct for the feeder.

**Low-tension distributing mains** having three conductors of the same size are preferable of single-conductor cable, to facilitate making service taps. This work must be done while the lines are alive, and is much more easily accomplished when one polarity may be dealt with at a time. The same is true of service cables.

**Transmission cables** are almost universally of the three-conductor type. Insulation is placed on each conductor sufficient for the voltage between phases, and then a layer is placed over all three conductors in addition, as shown in Fig. 58, to provide insulation to ground.

**211. Cable insulation.** Cables are insulated with rubber, varnished cambric, or oiled paper. Rubber insulation is used where frequent taps are made, as on distributing mains, but not generally for feeders and transmission lines. Varnished cambric has been used to some extent in recent years as a substitute for rubber. Oiled paper is used almost exclusively for feeders and transmission lines, and can be used for primary distribution if the joints are well made and the ends are protected by suitable potheads.

Digitized by Google

**212. Thickness of cable insulation.** The smaller low-tension cables are provided with about $\frac{4}{32}$-in. insulation between conductors and lead; this is the least which it is advisable to use for mechanical reasons and is sufficient for 600 volts. In cables of 350,000 cir. mils to 1,500,000 cir. mils, it is customary to provide $\frac{5}{32}$ in. to $\frac{6}{32}$ in. of insulation, to insure sufficient mechanical strength to stand handling during installation. A thickness of $\frac{6}{32}$ in. is found sufficient for 2,000-volt to 6,000-volt single-conductor cables up to No. 4/0 A.W.G., while $\frac{10}{32}$-in. is required for potentials from 9,000 volts to 13,000 volts.

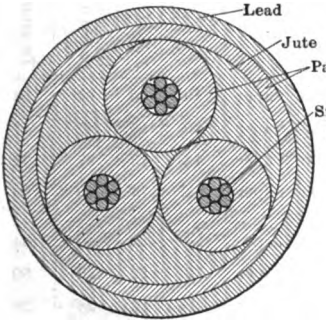

FIG. 58.—Cross-section of high-tension cable.

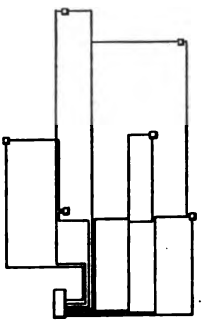

FIG. 59.—Lay-out of through cable lines to avoid the same routes.

**213. The insulation provided in transmission cables** in large transmission systems varies from 66 mils per 1,000 volts between conductors, at 6,600 volts, to 22 mils at 25,000 volts; and from 52 mils per 1,000 volts between conductor and ground, at 6,600 volts, to 16 mils at 25,000 volts.

**214. Selection of duct position for cables.** In placing cables in the duct-system a uniform method of selecting ducts should be followed as far as possible. Cables used in local distribution should be given a place, preferably in the top row, so that manholes can be built for service laterals without sinking them below the top row of ducts. Ducts should be selected for through lines so that they may be trained with the least interlacing with other cables. Lack of attention to this detail may result in a tangled condition of cables which greatly impedes any repair or reconstruction work.

**215. Routing of cable lines.** Through lines should be so routed as to utilize different duct lines to the best advantage. The service is better assured if transmission lines are separated as much as possible. This can be done by routing lines running to the same substation through different conduits, as indicated in Fig. 59.

**216. Installation of cable.** Cables are drawn into ducts by a line attached to a source of power. This line is put through the duct by the use of detachable rods of wood, which are pushed into the duct as they are joined together. They are then drawn through with the pulling-line attached, and disjointed as they come out. The cables are secured to the pulling-line by exposing the copper and making a secure mechanical connection, or by means of patent cable-grips, which are more quickly attached and removed.

The cable-pulling line is run over pulley-wheels leading out of the manhole to the source of power. Small-sized cable is wound on reels and cut to the

Digitized by Google

required length as it is drawn in; but a length of about 400 ft. of three-conductor high-voltage cable, or of 1,000,000-cir. mil feeder cable, fills a reel, and it is usual, therefore, to order such cable in lengths to fit.

**217. List of Operating Three-conductor, High-tension, Cable Installations**

(From High-tension Underground Electric Cables, by H. Floy)

| Name | Working voltage | Neutral grounded | Size of conductor B. & S. or C. M. | Insulation | Thickness of insulation | | | |

**218. Training.** The training of cable through manholes must avoid sharp bends, tangled relations with other cables and the possibility of injury by employes while working in the manhole. It is customary to support cables on iron racks hung on the walls. In some cases brickwork shelves are built around the walls, on which the cable is laid. It is usual to protect cables in manholes to prevent the communication of trouble to other cables. This is done by wrapping them with some fire-proofing material, or by the use of split tile. With large cables, the radius of bends should not be less than ten times the diameter of the cable. The shape of the manhole walls should be designed with this in view.

**219. Jointing or splicing.** In jointing single-conductor cables, the lead sheath is removed about 6 in. back from the end and enough insulation is cut away to permit a soldered connection to be made. When the connection is complete, the bare parts are wrapped with tape until the equivalent of the cable insulation has been applied. A lead sleeve which has previously been slipped back over one of the cables is now wiped on the two cable sheaths so as to enclose the joint. The air space around the joint is then filled with hot insulating compound poured into a small hole in one end of the sleeve; a similar hole is left open in the other end of the sleeve to allow air to escape. These holes are then closed by soldering. The joint should

Digitized by Google

be allowed to cool before it is moved, so that the compound will hold the parts rigidly in place.

In jointing three-conductor cables, the lead must be removed about 10 in. to facilitate the taping of the conductors (Fig. 60). In making joints for voltages of 6,600 volts and higher, it is important that as little air remain in the taping as possible. If paper tape is used, each layer should have compound poured over it before the next is applied.

The jointer requires the services of a helper in preparing the lead sleeves, heating solder and compound, and guarding the entrance to the manhole. A three-conductor high-tension joint in a paper cable usually requires about 4 hr. to complete, two joints a day being a fair rate of progress in such work.

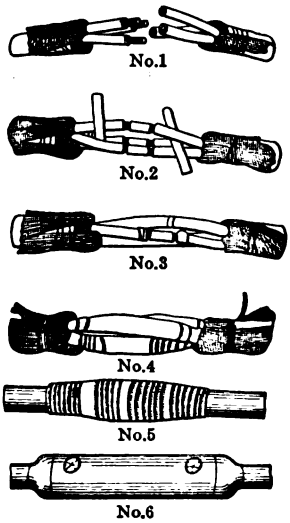

FIG. 60.—Cable splicing.

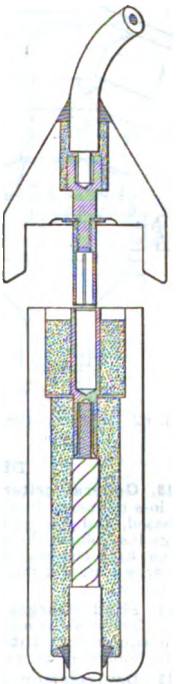

FIG. 61.—Porcelain pothead; single conductor type.

**220. Pole terminals.** In many primary distributing systems, it is usual to run feeders and important mains underground for some distance from the station, and connect with overhead lines in the more scattered areas. This class of distribution requires that the cable ends which are brought up the pole to the overhead lines be properly protected by **cable terminals or potheads.** Various types of terminal are in use, some of which include means for connecting and disconnecting the overhead line. Many such distributing systems have been equipped with porcelain potheads which have been very successful in protecting cables. The first such device was designed for a single-conductor cable, as illustrated in Fig. 61. The insulation is hermetically sealed by filling the porcelain sleeve with compound. The cap sheds all water and may be safely handled by a lineman when the line is alive. The connectors provide means for readily opening and closing the circuit when necessary for repair or alteration work. Other forms

Digitized by Google

have been devised for multiple-conductor cables, in which there is a pot of cast iron with porcelain tubes set into the cover (Fig. 62).

**221. Subway junction boxes.** The arrangement of junction boxes and similar accessories in manholes should be worked out so as not to obstruct the space needed for the cables. Low-tension junction boxes are of two types, one of which is mounted on the wall in a vertical position, while the other is placed in the roof of the manhole so that it is accessible for replacing fuses or cleaning contacts from above ground. The surface type has its advantages in districts where the drainage of manholes is not perfect.

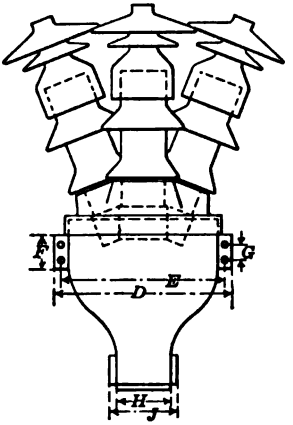

FIG. 62.—Cable pothead; triplex type.

**222. Branch-line junction boxes.** In a primary distributing system in which mains are underground, it is necessary to have means by which branches may be disconnected, without shutting down the circuit, when a transformer is to be connected or a cable repaired. Subway junction boxes with copper connections have commonly been applied to this work. The parts of the cable from which the lead has been removed are sealed in from moisture by wiped sleeves, or by filling the lower part of the box with hot compound. The **porcelain pothead** (Par. **220**) has also been found convenient for this purpose, in manholes, as the cap may be submerged without permitting water to reach the live parts.

## DISTRIBUTION ECONOMICS

**223. General criterion for most economical size of conductor.** The loss of energy in a conductor diminishes as the size of the conductor is increased, and *vice versa*. The generating capacity required to supply the energy loss follows the same law. The size of conductor with which the sum of the fixed charges on conductor and generating capacity, plus the value of energy loss, is a minimum, is the one which it is the most economical to employ.

**224. Fixed charges** consist of interest, depreciation, taxes and insurance. These are computed at different rates, depending upon the character of the equipment. **Interest** should be figured at not less than the rate paid on the bonded debt, which is about 5 per cent. (Sec. 25).

**225. Depreciation** is based upon the working life of the equipment, allowing for changes in the state of the art, and the scrap value of the equipment when taken out of service.

**Weather-proof wire** consists of about 80 per cent. copper and 20 per cent. insulation. It is conservative to figure 7 per cent. on the insulation, or 1½ per cent. of the whole wire, with 1 per cent. added for the labor of replacing, making a total of 2½ per cent. of the original cost of the wire. **Poles** have a life of about 15 years, with little salvage value. Other overhead **line material** must be replaced at intervals of 5 to 10 years. The average rate for **overhead lines** may thus be taken at about 5 per cent.

The life of lead-sheathed paper or rubber **cables** is indeterminate, but this may be conservatively taken at 15 years. The junk value is comparatively high, as the copper and the lead sheath constitute a considerable percentage of the cross-section of the cable. It is, therefore, safe to estimate depreciation at 3 per cent. for cables of No. 4/0 A.W.G. and larger, and at 5 per cent. for the smaller sizes.

**226. Taxes and insurance** must be considered as fixed charges of the same class as interest and depreciation. They vary somewhat with the locality, but are usually from 1.5 per cent. to 2 per cent., total.

Digitized by Google

**227. The total fixed charges on underground cable and conduit** may be taken at 5 per cent. interest, 4 per cent. depreciation, and 1 per cent. taxes, a total of 10 per cent. The total rate on the average overhead system may be taken at 5 per cent. interest, 5 per cent. depreciation, and 1 per cent. taxes, a total of 11 per cent.

**228. General formula for annual conductor costs.** The cost of a conductor varies inversely as its resistance per unit length, and the value of energy and generating capacity to supply it vary directly as the resistance per unit length. The total annual cost is

$$Y = \frac{a}{R} + bR + cR \qquad \text{(dollars)} \qquad (15)$$

in which $a$, $b$ and $c$ are constants depending on the cost of the conductor and the cost of energy. These are determined as follows: Par. **229** to **230**.

**229. Formula for annual fixed charges on wire.** The cost of insulation varies approximately with the size of the conductor. For bare wire the product of weight per 1,000 ft., $W$, by resistance per 1,000 ft., for all sizes, is $WR = 32$; with weather-proof insulation $WR = 38$ for the sizes No. 4 to No. 0 A.W.G., or 36 for sizes from No. 2/0 to 350,000 cir. mils. The value of 1,000 ft. of conductor at 15 cents per pound is $0.15W$ dollars. Hence, when $W = 38/R$, the cost per conductor of a circuit $L$ thousand feet long is

$$C_1 = 0.15WL = \frac{0.15 \times 38L}{R} \qquad \text{(dollars)} \qquad (16)$$

Taking the fixed charges at 9 per cent., the annual cost is

$$C_1 = \frac{0.09 \times 0.15 \times 38L}{R} = \frac{0.513L}{R} \qquad \text{(dollars)} \qquad (17)$$

Thus $a = 0.513L$, in this case (Eq. 14).

**230. Formula for annual fixed charges on single-conductor cable.** With underground conductors a change in the size of the conductor does not make a proportionate change in cost. The table in Par. **232** gives the cost per 1,000 cir. mils of various sizes of single-conductor and three-conductor lead-sheathed cables. The resistance per 1,000 cir. mils per 1,000 ft. of copper at ordinary temperatures is about 10.4 ohms. If $M$ is the number of 1,000 cir. mils and $P$ is the price per 1,000 cir. mils, the cost of a single-conductor cable is $MP$. $M = 10.4/R$ and the cost of the cable is $10.4PL/R$, where $L$ is the number of thousands of feet.

For **single-conductor low-tension cable** the value of $P$ averages $1.20 for cables from No. 2/0 A.W.G. to 500,000 cir. mils, and the value of each conductor is

$$C_2 = \frac{10.4 \times 1.2L}{R} = \frac{12.48L}{R} \qquad \text{(dollars)} \qquad (18)$$

Taking the fixed charges at 9 per cent., the annual conductor cost is

$$C'_2 = \frac{0.09 \times 12.48L}{R} = \frac{1.12L}{R} \qquad \text{(dollars)} \qquad (19)$$

and in this case $a = 1.12L$ (Eq. 14).

**231. Formula for annual fixed charges on three-conductor cable.** In the case of three-conductor cables the cost per 1,000 cir. mils in Par. **232** is based on the total cross-section of the three conductors. The cost of three-conductor cable is

$$C_3 = \frac{3 \times 10.4PL}{R} \qquad \text{(dollars)} \qquad (20)$$

and the annual charges are

$$C'_3 = \frac{0.09 \times 3 \times 10.4PL}{R} = \frac{2.8PL}{R} \qquad \text{(dollars)} \qquad (21)$$

and $a = 2.8PL$. Thus the value of $a$ may be derived for different kinds of cable and at various values of copper, lead and insulation. Where a circuit is composed of more than one cable, this must be taken into account in figuring the total annual cost for the circuit; that is, for a two-wire circuit the value of "$a$" is doubled and for three cables it is trebled.

**233. Fixed charges on generating equipment.** Where conditions are such that generator capacity could be released for commercial load by the use of larger conductors, the fixed charges on generating equipment should be considered one of the elements of annual cost of a circuit. The station capacity required to supply the energy loss at the time of the maximum load $I$ is $I^2RL/1{,}000$, in kw. The value of station capacity required to supply the loss on a feeder, when the cost is $100 per kw., is

$$C_4 = \frac{100 \times I^2RL}{1{,}000} \qquad (22)$$

and the fixed charges per conductor at 12 per cent., are

$$C'_4 = 0.12 \times 0.1 I^2RL = 0\ 012 I^2RL \quad \text{(dollars)}$$

and $b = 0.012 I^2L$ (Eq. 14).

**234. Energy loss.** The loss of energy on a circuit during a year is dependent upon the annual load factor of the load carried. In Fig. 63 typical load curves are shown for a lighting feeder which carries some day motor-load, for the months of March, June, September, and December. The energy losses will evidently be different on this feeder each month in the year, being less during the summer months than during the winter months.

**The annual loss** on a circuit may be computed with sufficient accuracy for practical purposes as follows: Take an average day in March, and compute the value of $I^2R$ for each hour. Repeat this operation for the June, September and December curves. Multiply the sum of the losses on the four curves by 91, this being the number of days in each quarter of the year. This total is the annual loss in kilowatt-hours.

**235. Loss factor.** The ratio of the loss as thus calculated, to the value of the loss if the feeder had carried the maximum load of the year every hour of the year, may be called the loss factor, just as the ratio of the actual output for the year, to the possible output at the rate of the maximum load, is called the load factor of a circuit. If the loss factor of the feeder is 20 per cent., the annual loss is

$$\frac{I^2R \times 0.2 \times 365 \times 24}{1{,}000} = 1.752 I^2R \quad \text{(kw-hr.)} \qquad (23)$$

The loss factor for a load having the characteristics illustrated in Fig. 63 is about 16 per cent.

**236. Calculation of loss.** Given the character of the load curve, the loss factor may be determined in the manner described (Par. **234** and **235**) and the annual loss of energy calculated from the maximum load $I$, in terms of $R$, the resistance per 1,000 ft. of conductor. The loss at the time of the annual maximum load being $I^2RL$, the annual loss is

$$\frac{I^2RL \times 8{,}760 \times F}{1{,}000} \quad \text{(kw-hr.)} \qquad (24)$$

Digitized by Google

where $F$ is the loss factor. The loss equals $1.40I^2RL$ kw-hr. when the loss factor is 16 per cent. The value of this energy may be taken at about 1 cent per kw-hr. in the smaller plants, 0.7 cent in the larger engine-driven plants and 0.5 to 0.3 cent in the turbine-driven plants. At 1 per cent. per kw-hr. the value of the annual energy loss per conductor, at 16 per cent. loss factor, is

$$C_5 = 0.0140I^2RL \quad \text{(dollars)} \quad (25)$$

and the constant $c$ is equal to $0.0140I^2L$.

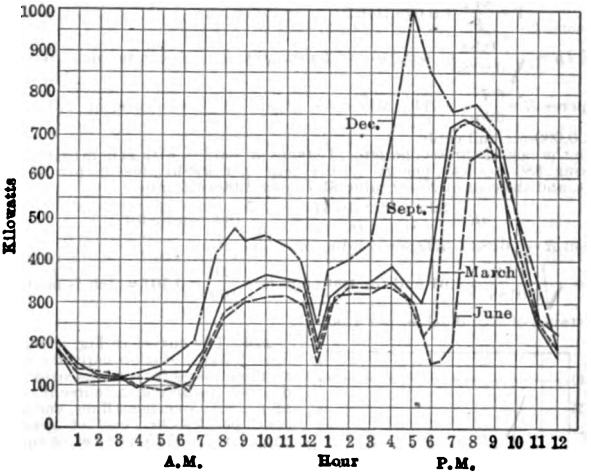

FIG. 63.—Typical load curves.

**237. Summary of annual conductor costs; condition for minimum.** The total annual cost is, therefore, the sum of the three quantities $a/R$, $bR$, and $cR$ (Eq. 14). For weather-proof wire, with station capacity at $100 per kw., a loss factor of 16 per cent., and energy at 1 cent per kw-hr., the annual cost is

$$Y = \frac{a}{R} + bR + cR = \frac{0.513L}{R} + 0.012I^2RL + 0.014I^2RL = \frac{0.513L}{R} + 0.026I^2RL \text{ (dollars)} \quad (26)$$

It is desired to ascertain at what value of $R$ the sum of these three elements will be a minimum for a given current, at the time of the annual maximum load. The only variable in the equation being $R$, the value of $Y$ will be a minimum, according to the rule of the calculus, when $\partial Y/\partial R = 0$.

If $Y = \frac{0.513L}{R} + 0.026I^2RL$, then $\frac{\partial Y}{\partial R} = \frac{0.026I^2R^2L - 0.513L}{R^2} = 0$. Therefore, $0.026I^2R^2L = 0.513L$, and $I^2R^2 = 0.513/0.026 = 19.7$; whence $IR = \sqrt{19.7} = 4.44$. For instance, if $I = 100$ amp., $R = 0.0444$ ohm, which is about the resistance per 1,000 ft. of a No. 4/0 conductor.

**238. Examples of calculation of most economical size of conductor.** Assume generating capacity costing $80 per kw., energy at 0.4 cent per kw-hr. and the loss factor at 25 per cent. With single-conductor low-tension

Digitized by Google

cable of 500,000 cir. mils to 1,000,000 cir. mils, the cost per 1,000 cir. mils averages 90 cents per 1,000 ft., Par. 232.

Hence $\frac{a}{R} = \frac{0.09 \times 10.4 \times 0.9\,L}{R} = \frac{0.84L}{R}$,

$$bR = \frac{80 \times 0.12 I^2 RL}{1{,}000} = 0.0096 I^2 RL,$$

$$cR = \frac{0.004 \times 8{,}760 \times 0.25 I^2 RL}{1{,}000} = 0.0087\ I^2 RL.$$

$$Y = \frac{84\,L}{R} + 0.0183 I^2 RL.$$

and $IR = \sqrt{\frac{0.84}{0.0183}} = \sqrt{46} = 6.7$ per 1,000 ft. of conductor. With 600 amperes $R = \frac{6.7}{600} = 0.011$, which is about the resistance of 1,000 ft. of 1,000,000-cir. mil cable.

In the case of three-conductor, 10,000-volt cables, with generating capacity costing $80 per kw., energy at 0.4 cent per kw-hr., loss factor at 25 per cent. and the cost of No. 0 cable $1.75 per 1,000 cir. mils,

$$aR = \frac{\$2 \times 0.09 \times 10.4L}{R} = \frac{1.87}{R} \text{ per conductor.}$$

$(b+c)\ R = 0.0183\ C^2 RL$ per conductor. Therefore

$CR = \sqrt{\frac{1.87}{0.0183}} = 1.01$ and for 100 amp. $R = \frac{1.01}{100} = 0.101$ which is nearest the resistance of No. 0 cable, per 1,000 ft.

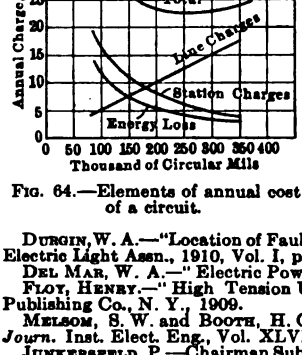

FIG. 64.—Elements of annual cost of a circuit.

**239.** The curves in Fig. 64 show the line charges, station capacity charges and line losses for various sizes of conductor, assuming a current of 100 amp., with overhead lines, energy at 1 cent. per kw- hr., cost of generating capacity at $125 per kw. of capacity, and loss factor 12 per cent.

# SECTION 13

## INTERIOR WIRING

### RELATION OF WIRING TO FIRE RISK

**1. The National Electrical Code** was originally drawn in 1897, as the result of the efforts of the National Conference on Standard Electrical Rules, which comprised delegates from the various insurance, electrical, architectural and allied interests of the United States. The object of the conference was to formulate a set of rules for the installation and construction of electrical apparatus *in a manner free from fire hazard.* The *National Electrical Code* was the result of their work. This was immediately accepted as a standard and adopted by the National Board of Fire Underwriters. It at once placed electric lighting on a safe basis. At present practically all wiring is in accordance with Code rules; the fire insurance policies in some states and communities expressly provide that the Code shall be followed in detail. The National Conference on Standard Electrical Rules has disbanded and the work of the Underwriters' National Electrical Association and the National Conference has been taken over by the National Fire Protection Association, in which are represented the following organizations: American Electric Railway Association; American Institute of Electrical Engineers; Associated Factory Mutual Fire Insurance Cos.; National Board of Fire Underwriters; National Electric Light Association; National Electrical Contractors Association; National Electrical Inspectors Association.

Periodically the National Fire Protection Association convenes and makes such revisions or additions to the Code as are required by advances in the art. The *National Electrical Code* is revised every 2 years and a supplement and a "List of Approved Fittings," are issued semi-annually. Either of these can be obtained gratis on application to any of the Underwriters' Association offices or to any local inspection bureau.

**2. Legal status of the Code.** The Code has no statutory force, but merely comprises the rules and requirements of the National Board of Fire Underwriters. However certain cities have passed ordinances providing that all work installed in such cities shall be in accordance with the Code, which gives it a legal status in these cities. Moreover, other cities have legalised requirements of their own, which are, usually, essentially the same as the Code requirements. Where requirements are authorized by ordinance or statute they, of course, take precedence over the Code rules.

**3. The National Code rules are of great economic importance** in relation to fire hazard and fire insurance; without question fire loss amounting to many thousands of dollars has been averted by their use. When installing any electrical equipment, the first step should be to ascertain whether there are local installation rules (ordinances) in force in the community. If there are such rules, they should be followed; if there are none, the *National Electrical Code* rules should be followed.

**4. Inspection.** All electrical installations should be inspected, whenever an experienced inspector is available, to insure that they comply with either local or Code rules. In cities where rules have been adopted by ordinance, such inspection is usually mandatory. Where inspection is not mandatory, it is always advisable to retain an inspector from the most convenient Underwriters' Bureau to examine the work while it is being installed. Nominal fees are charged for such inspection.

Digitized by Google

All fittings and materials used in wiring installations should be approved by the Underwriters' Laboratories. Practically all standard equipment now being marketed is so approved and, usually, is so marked. When in doubt one should consult the "List of Electrical Fittings" referred to above.

## METHODS OF WIRING

**5. Wiring methods may be classified thus:** (a) open or surface. wiring; (b) concealed knob and tube wiring; (c) wooden-moulding wiring; (d) metal-moulding wiring; (e) flexible-tubing or circular-loom wiring; (f) rigid iron-conduit wiring; (g) flexible metallic conduit wiring; (h) flexible steel-armored cable wiring.

**6. Open wiring on knobs and cleats** (Fig. 1) is a cheap and satisfactory method if installed in compliance with Code requirements, and is largely used in industrial plants and in mercantile establishments where appearance is of small moment. Single-braid, rubber-covered or slow-burning weather-proof wire may be used. Wires having slow-burning insulation must not be used in damp places. The wires must be supported every 4.5 ft. (1.37 m.) except in buildings of "mill" construction where, if an inspector's authorization is secured, they may be supported at every beam, provided that the wires are No. 8 or larger and are carried at least 6 in. (15.2 cm.) apart. In dry places for voltages below 300, the wires must be separated at least 2½ in.

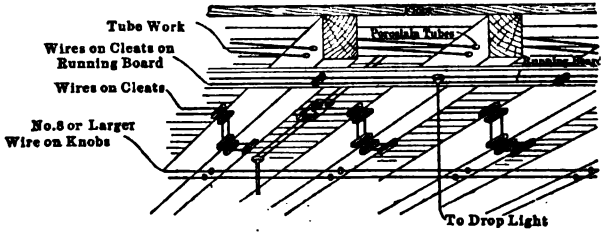

FIG. 1.—Methods of supporting open wiring.

(6.35 cm.), and they must be at least 0.5 in. (1.27 cm.) from the surface wired over. For voltages between 300 and 550, wires must be at least 1 in. (2.54 cm.) from the surface and must be separated 4 in. (10.2 cm.). In damp places, for voltages below 300, wires must be held 1 in. (2.54 cm.) from the surface. Where wires are exposed to mechanical injury protection must be afforded as specified by the Code. Wires must also be protected by porcelain tubes where they pass through walls, timbers or partitions. See the *National Electrical Code* for other minor requirements.

**7. Knob and tube wiring** (Fig. 2) is used in frame buildings, and is the cheapest method of concealed wiring. Although it has given fair satisfaction, it is being superseded by rigid conduit in progressive communities. In some cities only rigid iron or flexible conduit or flexible steel-armored cable is approved for concealed work.

The single-braid, rubber-insulated conductors are carried within the floors, walls and partitions of the building. Where passing through timbers they must be insulated with porcelain tubes. On a vertical run the wires must be protected from plaster droppings by tubes which extend at least 4 in. (10.2 cm.) above the horisontal timbers which have been pierced.

In structural-steel mill-type buildings, open wiring is carried on porcelain knobs or cleats which may be secured with stove bolts at points where there are spaces between the members or where holes are already punched. Sometimes it is desirable to screw the cleats to blocks which are clamped to the members with hook bolts.

Open work is especially suited to locations which are damp or hot such as dye works, breweries, dry kilns, metal refineries and the like. In such

Digitized by Google

installations special precautions must be observed; these precautions are fully described in treatises on wiring.

Within partitions and floors, where the wires are carried on knobs, the knobs must be spaced not more than 4.5 ft. (1.37 m.); the wires should be spaced at least 5.5 in. (14.0 cm.) and should be carried on separate timbers. They

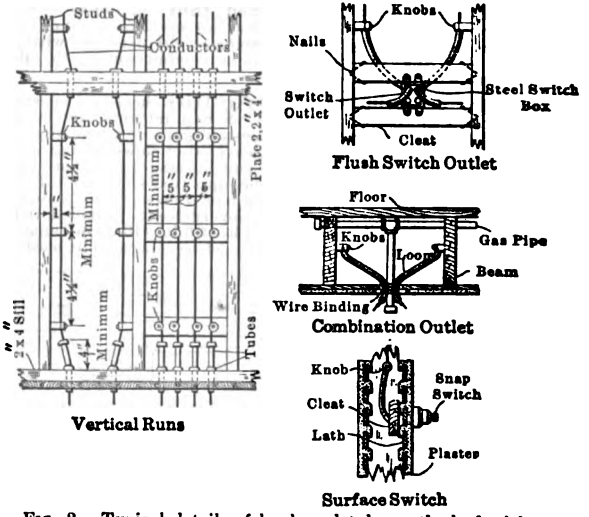

FIG. 2.—Typical details of knob and tube method of wiring.

may be close together if encased in flexible tubing. Only split knobs may be used for conductors smaller than No. 8; either split or tie knobs may be used for larger conductors. Tie wires must have the same insulation as the wires they support, and must not be smaller than No. 14. Flexible tubing must be used to protect conductors at each outlet, and must extend from the last point of support into the outlet box in one continuous length. Sheet-steel boxes must be used for flush-switch outlets. Fig. 2 shows typical details of the knob and tube method.

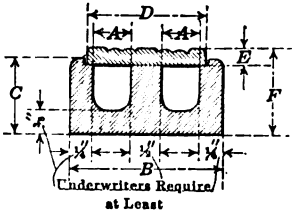

FIG. 3.—Standard, two-wire, wooden moulding.

**8. Wooden moulding** is, as a rule, only used for making additions to existing installations where good appearance is a consideration but where running the conductors concealed is either impossible or else prohibitive because of cost. Wooden moulding wiring is not approved for damp places or where the difference of potential between any two wires of the same system exceeds 300 volts. Single-braid rubber-covered wire is required, and no joints or splices are permitted except at outlets and at fittings. There are many styles of approved moulding fittings and almost any conceivable combination of connections can be realised.

Digitized by Google

**9. Dimensions and capacities of wooden mouldings.** Below are given the dimensions of standard two-wire wooden mouldings; the products of various manufacturers vary somewhat. All dimensions are given in inches (Fig. 8). (Kirkpatrick Mfg. Co.)

| A Size of groove | Will accommodate wires | | B | C | D | E | F |
|---|---|---|---|---|---|---|---|
| | Solid | Stranded | | | | | |
| 0.250 | 14 to 12 | ..... | 1½ | ⅜ | 1½ | 3/16 | ⅜ |
| 0.375 | 10 to 8 | 8 | 1¾ | ¾ | 1⅝ | 7/32 | ⅜ |
| 0.500 | 9 to 4 | 5 to 6 | 2¼ | 1 | 1⅝ | 11/32 | 1 |
| 0.625 | 3 to 0 | 4 to 1 | 2¾ | 1 3/16 | 1⅞ | 7/16 | 1¼ |
| 0.750 | ..... | 0 to ⅜ | 2¾ | 1½ | 2 3/16 | ¼ | 1⅜ |
| 0.875 | ..... | ⅜ to 250,000 | 3¼ | 1⅝ | 2 7/16 | ¼ | 1½ |
| 1.000 | ..... | 250,000 to 500,000 | 3¼ | 1⅝ | 2 13/16 | ¼ | 1¾ |

**10. Metal moulding,** which can be used only for exposed circuits, is now largely employed in the place of wooden moulding (Par. 8). It also finds application in new construction in commercial buildings and in industrial plants, being substituted for the open wiring method. This moulding occupies little space (see Fig. 4), is very neat in appearance and being sherardized, will take paint readily. The conductors in the moulding can be taken out for inspection at any time with little trouble. Alterations in or additions to the moulding system can be very easily and neatly made. Fittings are manufactured, whereby almost any possible wiring arrangement can be effected. See *National Electrical Code* and manufacturers' catalogues for further information. Metal-moulding wiring costs somewhat less than conduit and. for exposed work, provides a neater ap-

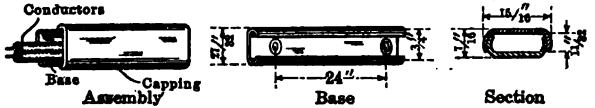

FIG. 4.—National metal moulding.

pearance. It can be used only where the potential difference does not exceed 300 volts and the power 660 watts. It must be continuous from outlet to outlet or to approved fittings. It should not be used in damp places.

Single-braid, rubber-insulated wire can be used in metal moulding. Wires must be laid in—not fished. The moulding shown in Fig. 4 has a capacity for four No. 14 wires. All wires of an alternating-current circuit must be in the same moulding, and it will be found advantageous to treat direct-current circuits likewise.

**11. Flexible tubing (circular loom, duraduct, etc.)** is now seldom used except in combination with other methods of wiring. However, it is very useful and finds wide application for furnishing additional insulation and protection to conductors. It cannot be used in damp places. See *National Electrical Code* for further information. Where metal outlet boxes or switch boxes are used, flexible tubing must extend from the last porcelain support into the outlet box. It is used for encasing wires fished between walls and ceilings, each wire being separately encased. It is also used in open work where wires, are nearer each other than 2.5 in.; on wires crossing other wires, gas pipes, water pipes, iron beams, wood work, brick or stone; on wires at chandeliers and bracket outlets; on gas pipe back of insulating joints; on wires under the edges of canopies: Where space is limited and the 5-in. separation required between wires cannot be maintained, each wire must be separately encased in a continuous length of flexible tubing. Flexible tubing may also be employed as an added protection to wires; as for instance on portable wires around machinery and in show windows, etc., where added protection, although not required, is often desirable.

Digitized by Google

Below are given the dimensions of one standard line of flexible tubing, or circular loom, which has been approved by the Underwriters' Laboratories.

**13. Typical Dimensions of Flexible Tubing (Circular Loom)**

| Inside diam., inches | Outside diam., inches | Ft. per coil | Largest wire, A.W.G., and cir. mils | Weight per 1,000 ft.-lb. |
|---|---|---|---|---|
| $\frac{3}{8}$ | $\frac{11}{32}$ | 250 | No. 14 | 75 |
| $\frac{1}{2}$ | $\frac{7}{16}$ | 250 | No. 12 | 110 |
| $\frac{3}{4}$ | $\frac{5}{8}$ | 200 | No. 8 | 125 |
| $\frac{7}{8}$ | $\frac{3}{4}$ | 200 | No. 4 | 155 |
| $\frac{3}{4}$ | $1\frac{1}{16}$ | 150 | No. 2 | 200 |
| 1 | $1\frac{5}{16}$ | 100 | No. 00 | 275 |
| $1\frac{1}{4}$ | $1\frac{5}{8}$ | 100 | 200,000 | 360 |
| $1\frac{1}{2}$ | $2\frac{1}{16}$ | 100 | 400,000 | 400 |
| $1\frac{3}{4}$ | $2\frac{1}{4}$ | 100 | 600,000 | 440 |
| 2 | $2\frac{3}{4}$ | Odd lengths | 800,000 | 600 |
| $2\frac{1}{2}$ | 3 | Odd lengths | 1,100,000 | 700 |
| $2\frac{1}{2}$ | $3\frac{1}{2}$ | Odd lengths | 1,300,000 | 700 |

**13. Rigid iron conduit wiring** (Par. 14, 15 and 17) is approved for both exposed and concealed work in practically all classes of buildings. It provides the safest and most satisfactory method of electric wiring yet developed. Though highest in first cost of all of the methods it is probably the most economical for permanent installations. In the most progressive cities, only rigid or flexible iron conduit or steel-armored cable is permitted for concealed work. Rigid iron conduit should have the preference in every case of permanent installation except where the work is exposed, in which event metal moulding is usually preferable.

Iron conduit and fittings are finished black, similar to enamel, or are zinc-coated. The black finish is the most popular, but the zinc-finished conduit should be used for outdoor installations, in damp places or when the conduit is imbedded in cement. Conduit is merely standard-weight steel pipe, specially treated; hence conduit dimensions and threads are the same as those for corresponding sizes of wrought-iron pipe. Refer to the *National Electrical Code* for complete rules for conduit installations.

**14. Iron conduit fittings.** Outlet and switch boxes, elbows, supports, hangers and other conduit fittings are manufactured in almost endless variety, and can be procured to meet practically any condition. See manufacturers' catalogues and the *National Electrical Code*.

**15. Wire for use in iron conduit** must be double-braid, rubber-covered and must be continuous (without splices) from outlet to outlet. For alternating-current circuits, all the wires of one circuit must be carried in the same conduit to eliminate heating due to electromagnetic induction.

**16. Flexible metallic conduit** (Fig. 5) is approved for the wiring of practically all classes of buildings. It is used principally for wiring finished buildings, in cities where iron conduit is required, or where a thorough job is desired. It is used for wiring near machinery, and in other locations where the conduit run changes direction frequently, or where the wires must be fished. It is also useful in wiring new frame buildings because it can be easily bent in any direction; however, rigid conduit is cheaper and more frequently used for this service. It can be installed more readily than can rigid conduit, which is manufactured in lengths of 10 ft. Flexible metallic conduit is furnished in coils of from 25 to 250 ft., depending upon the conduit size. The wire and the general installation requirements are practically the same as for rigid conduit. Many fittings for flexible metallic conduit are manufactured, although no elbows are required.

FIG. 5.—Greenfield flexible-steel conduit.

**17. Standard Sizes of Conduits for the Installation of Wires and Cables** (*As adopted, recommended and copyrighted by The Natl. Electrical Contractors Assn. of the U. S.*)

Conduit sizes based on the use of not more than three 90-deg. elbows in runs taking up to and including No. 10 wires, and two elbows for wires larger than No. 10. Wires No. 8 and larger are stranded. Special permission is required of the inspection department having jurisdiction for the installation of more than nine wires in the same conduit. The wires used by the telephone companies of various cities differ as to thickness of insulation. The table "*A*" gives values satisfactory for both light and heavy insulation. For explanation of column reference letters for table "A," see footnotes.

| Size of wire | | Single wires | | | | Duplex wires | | | Single wires | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | | | | | Convertible system | |
| A.W.G. | Circular mils | Single wire | Two-wire system | Three-wire system | Four-wire system | Size A.W.G. | Number of wires | Size of conduit | Number and size of wires, A.W.G. | Size of conduit |
| 14 | 4,107 | ½ | ½ | ½ | ½ | 14 | 1 | ½ | 1– 10 | ¾ |
| 12 | 6,530 | ½ | ½ | ½ | ½ | 14 | 2 | ½ | 2– 14 | ¾ |
| 10 | 10,380 | ½ | ½ | ½ | 1 | 14 | 3 | 1 | 1– 8 | ¾ |

*a*. No. 14 R. C. double-braid solid wires. Based on straight run without elbows.

*b*. No. 16 light insulation fixture wires. Based on straight run without elbow.

*c*. No. 18 light insulation fixture wires. Based on straight run without elbow.

*d*. No. 20 braided and twisted pair. Switchboard or desk instrument wire. Based on not more than two 90-deg. elbows.

*e*. No. 19 braided and twisted pair. Standard $\frac{1}{64}$-in. insulation, telephone wire. Based on not more than two 90-deg. elbows.

**18. Flexible steel-armored conductor** (Fig. 6) has found considerable application during the last few years, due to its adaptability for electrical construction in finished buildings. It can be run with practically no regard for pipes or other grounded obstructions and can be fished long distances. It is more expensive than conductors in circular loom but it makes a thoroughly dependable job. Flexible steel-armored conductor consists of rubber-insulated wire or cable, protected from injury and to some extent from dampness by two layers of spirally wound flexible steel armor. It is manufactured "leaded" and "unleaded." The leaded conductor has

Digitized by Google

a lead sheath between the armor and the rubber to exclude dampness. Both types are made in any reasonable gage of wire or cable. The leaded type is approved for use in all classes of buildings and can be installed during or after their construction. The unleaded type is approved only for use in locations that will not be permanently damp.

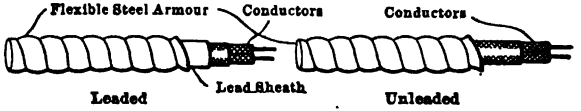

FIG. 6.—Flexible steel-armored conductor.

**19. Relative Costs of Various Methods of Wiring** ("Electric Light Wiring," C. E. Knox)

| Method of wiring | Relative cost in per cent. |
|---|---|
| Conduit (rigid iron) | 100 |
| Moulding (fire-proof wood) | 80 |
| Flexible metallic conduit | 80 |
| Flexible steel-armored cable | 70 |
| Moulding (hardwood) | 65 |
| Moulding (soft wood) | 50 |
| Open wiring (knob and cleat) | 40 |
| Flexible tubing | 40 |
| Concealed knob and tube | 35 |

The values given are approximate for average conditions. They include all labor and material for "roughing in" but do not include lamps, fixtures, switches or accessories.

## WIRES AND CABLES

**20. Electric wire and cable terminology.** (*U. S. Bureau of Standards Circular No.* 37.)

**Wire.** A slender rod or filament of drawn metal. The definition restricts the term to what would ordinarily be understood by the term "solid wire." If a wire is covered with insulation, it is properly called an insulated wire; in general the term "wire" will be understood to include the insulation.

**Conductor.** A wire or combination of wires not insulated from one another, suitable for carrying a single electric current.

**Stranded Conductor.** A conductor composed of a group of wires or any combination of groups of wires. The wires in a stranded conductor are usually twisted or braided together.

**Cable.** (1) A stranded conductor (single-conductor cable); or (2) a combination of conductors insulated from one another (multiple-conductor cable). The component conductors of the second kind of cable may be either solid or stranded, and this kind of cable may or may not have a common insulating covering. A small cable is called a "stranded wire" or a "cord," both of which are defined below. Cables may be bare or insulated, and the latter may be armored with lead or with steel wires or bands.

**Strand.** One of the wires or groups of wires of any stranded conductor.

**Stranded wire.** A group of small wires, used as a single wire. A wire has been defined as a slender rod or filament of drawn metal. If such a filament is subdivided into several smaller filaments or strands, and is used as a single wire, it is called "stranded wire." There is no sharp dividing line of size between a "stranded wire" and a "cable." If substantially insulated, it is called a "cord," defined below.

**Cord.** A small cable, very flexible and substantially insulated to withstand wear. Usually the insulation of a cord contains rubber.

**Concentric strand.** A strand composed of a central core surrounded by one or more layers of helically laid wires or groups of wires.

**Concentric-lay cable.** A single-conductor cable composed of a central core surrounded by one or more layers of helically laid wires.

Digitized by Google

**Rope-lay cable.** A single-conductor cable composed of a central core surrounded by one or more layers of helically laid groups of wires. This kind of cable differs from the preceding in that the main strands are themselves stranded.

**N-conductor cable.** A combination of N conductors insulated from one another. (It is not intended that the name as here given be actually used. One would instead speak of a "3-conductor cable," a "12-conductor cable," etc. In referring to the general case, one may speak of a "multiple-conductor cable," as in definition for "*Cable*" above.)

**N-conductor concentric cable.** A cable composed of an insulated central conducting core with tubular stranded conductors laid over it concentrically and separated by layers of insulation. Usually only 2-conductor or 3-conductor. Such conductors are used in carrying alternating currents. The remark on the expression "N-conductor" given for the preceding definition applies here also.

**Duplex cable.** Two insulated single-conductor cables twisted together. They may or may not have a common insulating covering.

**Twin cable.** Two insulated single-conductor cables laid parallel, having a common covering.

**Triplex cable.** Three insulated single-conductor cables twisted together. They may or may not have a common insulating covering.

**Twisted pair.** Two small insulated conductors twisted together, without a common covering. The two conductors of a "twisted pair" are usually substantially insulated, so that the combination is a special case of a "cord."

**Twin wire.** Two small insulated conductors laid parallel, having a common covering.

**21. Specifications for insulated conductors** are given in detail in the *National Electrical Code*. Since these specifications are subject to revision, it is inadvisable to repeat them here. Practically all rubber-insulated wire on the market is manufactured in accordance with Code requirements, and to each coil is fastened a tag indicating the approval of the Underwriters' Laboratories. Unapproved rubber-insulated wire should not be installed.

**22. Allowable or Safe Current-carrying Capacities of Insulated Copper Wires**
(1913 *National Electrical Code*)

**26. Current-carrying capacity of copper wires.** If the current carried by a given conductor is too great, the conductor will become so hot that it will be unsafe, or may, if insulated, damage its insulation. Certain safe current values have been determined for different sizes of conductor, and are listed in Par. **22**. Less current is permissible in rubber-insulated

Digitized by Google

wires than in wires insulated with other materials because relatively low temperatures may injure rubber insulation. For interior wiring, the capacities recommended by the *National Electrical Code* in Par. **22** should be used, unless contrary local municipal rules are mandatory.

**27. Allowable current-carrying capacities of aluminum wire** are 84 per cent. of the values given in the table for copper wire (Par. **22**), assuming the same kind of insulation.

**28. Rubber-covered or rubber-insulated wires and cables** (Par. **23**, **24**, and **25**) when protected with one braid over the insulation, are known as single-braid wires, and when two braids are used in order to insure against injury by abrasion, they are known as double-braid wires. Rubber-covered conductors are used for concealed inside wiring or in damp places, and throughout where the voltage exceeds 550. Conductors insulated with less expensive materials (see following paragraphs) can be used out-of-doors on pole lines and inside in dry places where the wires are exposed. The *National Electrical Code* permits single-braid, rubber-covered wires for exposed interior wiring in damp places and in moulding. Double-braid, rubber-insulated conductors must be used in conduit.

**29. Weather-proof wire or cable** (Par. **34**) is used for out-of-door conductors and should be supported on porcelain or glass insulators and not on knobs, cleats or rubber hooks. Weather-proof Code wire is not approved for inside wiring except where exposed to corrosive vapors. The so-called "weather-proof" insulation becomes a reasonably good conductor when moist. Triple-braid weather-proof conductors have three braids, saturated with a so-called moisture-proof compound, served around them, and double-braid conductors have two such braids. Triple-braid weather-proof conductors are approved by the *National Electrical Code* for outside construction, but double-braid conductors are not approved at all.

**30. Slow-burning conductors** are insulated with three braids impregnated with a fire-resisting compound, as is used on slow-burning weather-proof conductors. The Code approves slow-burning conductors for interior exposed wiring, in dry places, where the voltage does not exceed 550. They are particularly applicable for hot, dry places where ordinary insulations would soon perish. The outer braid is finished like that of slow-burning weather-proof conductors, and has the same properties. See table Par. **34**.

**31. Slow-burning weather-proof conductors** (Par. **34**) are sometimes used for interior exposed wiring in damp places, where there are corrosive vapors provided that the voltage does not exceed 550. They are cheaper than rubber-insulated conductors. The insulation consists of an inner weather-proof coating and an outer fire-resisting coating. The Code requires that the fire-resisting coating be $\frac{1}{3}$ the thickness of the entire coating. To meet this condition the manufacturers use one weather-proof braid and two fire-resisting braids. The fire-resisting compound consists of a mixture containing white lead, oxide of zinc, chalk, or some similar substance. The outer braid is rubbed smooth on the outside. The manufacture of slow-burning weather-proof conductors has been discontinued by some manufacturers and they are now seldom used. Slow-burning weather-proof wire is cheaper than slow-burning wire. It is not suitable for out-of-door service. Wires with a fire-resisting outer coating have the advantage that dust and lint do not readily adhere to their outer surfaces, as is often the case with weather-proofed braids. If dust does collect, it can be easily swept off.

**32. Weather-proof, slow-burning conductors** have a fire-resisting coating next to the conductor and a weather-proof coating on the outside. They are not approved by the Code.

**33. Twin wires or cables** (Par. **35**) (sometimes called "conduit wires") are used where they are to be drawn into conduit and should never be used except in conduit or in metal moulding. Each wire is rubber insulated to the thickness indicated in Par. **23**, and then is served with a braid or with a tape. The two conductors are finally bound together parallel one with another, with a tenacious braid at least 0.0312 in. thick for wires larger than No. 10 B. & S. gage and 0.0125 in. for No. 10 B. & S. gage or less in size. This construction is considered in the *National Electrical Code* as equivalent to that of double-braid, rubber-covered wire. Twin conductors larger than No. 0000 should not be used because of their tendency to kink.

| 14 | 100 | 0.22×0.40 | | 100 | 0.23×0.42 | |

**36. Fibre-cored cables** (Par. 37). Alternating current flowing in large cables has greater density on the surface of the conductor than in the center (so-called skin effect) therefore an ordinary cable will not carry as high a value of alternating current as of direct current, with the same temperature rise. In order to overcome this it is advisable, on single-conductor cables 700,000 cm. and larger for 60-cycle circuits, and 1,250,000 cm. and larger for 25-cycle circuits, to strand the copper around a fibre core. The weight of copper in this type of cable is the same per ft. as in an ordinary cable, but owing to its annular cross-section the cable is much more efficient in alternating-current circuits and also has a somewhat greater current-carrying capacity due to the larger radiating surface. These copper strands can be covered with any desired type of insulation.

**37. Dimensions and Current-carrying Capacities of Fibre-cored Cables.** (*General Electric Co.*)

| Size cir. mils | Dia. fiber core, in. | No. of wires in strand | Size wire in strand, in. | Overall dia. copper core, in. | Ampere capacity | |
|---|---|---|---|---|---|---|
| | | | | | 30 deg. cent. rise | 60 deg. cent. rise |

| 750,000 | 0.312 | 48 | 0.125 | 1.060 | 750 | 900 |
| 700,000 | 0.281 | 51 | 0.117 | 0.99 | 700 | 830 |
| 50,000 | 0.250 | 45 | 0.1056 | 0.890 | 550 | 660 |

**38. Conductors with varnished cambric or oiled-cloth insulation** are made by manufacturers of large wire. The insulation consists of cloth which is impregnated with oil, dried and then wound spirally around the conductor to the required thickness. A braid or some other form of protection is served around the outside. Such conductors are largely used for voltages exceeding 2,400, but for lower voltages rubber insulation appears to be the best suited, and is used much more extensively than any other. The varnished cloth insulation has a tendency to unwind; this affords no trouble to wiremen who are familiar with its manipulation, but may cause the uninitiated some inconvenience.

## FITTINGS AND ACCESSORIES

**39. Snap switches.** Surface snap switches and flush snap switches are made for practically any service, and are procurable, in certain designs, for

Digitized by Google

voltages as high as 600. These include single-pole, double-pole and triple-pole switches; three-way or four-way switches, for the control of hall lamps from any one of several locations; and the electrolier switches. They can be obtained (for 250 volts) for currents as large as 30 amp. Snap

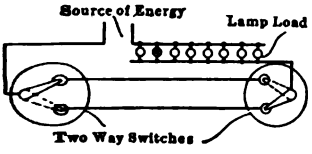

FIG. 7.—Control of circuit from two locations with two-way switches.

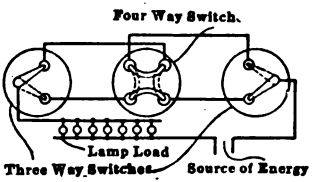

FIG. 8.—Control of circuit from any one of more than two locations.

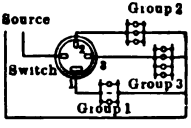
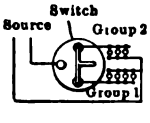
switches are usually preferable to knife switches from an operating standpoint as any one can operate them, under normal conditions, without drawing a destructive arc. Indicating switches, which show by their appearance whether they are open or closed, should always be used. Flush snap switches are installed in pressed-steel switch boxes which are set in walls or partitions, so that only the plate and operating buttons are visible. Types can be obtained which will furnish practically the same service as surface snap switches. They are more expensive but present a neater appearance than surface switches.



Three-Circuit Switch



Two-Circuit Switch

FIG. 9.—Wiring for electrolier switches.

**40. Three-way and four-way switches.** Switches for controlling a group of lamps from either of two locations are wired as indicated in Fig. 7. Two "three-way" snap switches are required. This scheme is largely used for the control of hall lamps. Switches for controlling a group of lamps from any one of more than two locations are connected as in Fig. 8. A "three-way" switch is used at each end of the circuit and as many additional "four-way" switches

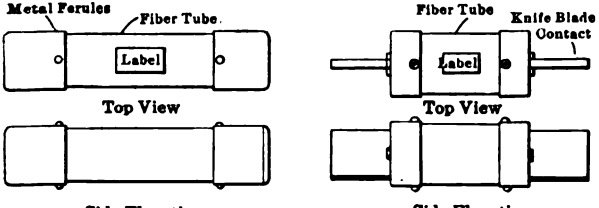


FIG. 10.—National Electrical Code standard enclosed fuses.

are necessary as there are additional control locations. This arrangement is used for hall lamps so that they can be controlled from any floor.

**41. Electrolier switches** (Fig. 9) control lamps in independent groups such as would be used in an illuminated dome or of an electrolier. Switches

Digitized by Google

are made for this service in the "flush," "surface" and "pull" types. Operation of the two-circuit switch is as follows: Position *A*, all lamps off; *B*, only those of group 1 are on; *C*, both groups on; *D*, only those of group 2 are on. With the next movement all lamps are extinguished. The sequence outlined is typical, but switches of all makes do not provide just this sequence. A three-circuit switch is necessary for controlling three groups. With one type, the sequence for the different positions is as follows: *A*, connects group 1; *B*, connects groups 1 and 2; *C*, connects groups 1, 2, and 3; *D*, disconnects all lamps.

**42. Open-link fuses** disrupt violently under conditions of short-circuit and blacken the panel that supports them. They are approved by the Code if supported on slate bases and enclosed in iron cabinets. When so arranged they render exceptionally good service in industrial plants if they are maintained by journeyman electricians.

**43. Cartridge or enclosed fuses.** The Code cartridge fuses (Fig. 10) are of two designs, the ferule-contact type for currents below and including 60 amp. at 600 volts, and the knife-blade contact type for currents of from 61 to 600 amp. at 250 volts and of from 61 to 400 amp. at 600 volts. See *National Electrical Code* for detail dimensions of fuses of different capacities. A cartridge fuse usually consists of a tube of fiber or some similar material which enshrouds the fuse link. The link terminals are connected to contact pieces at the ends of the tube. An insulating powder surrounds the link and fills the tube. In some forms the fuse link is encased in a small air chamber, as illustrated in Fig. 11. The formation of destructive arcs is prevented in fuses of the cartridge type and the fuses themselves are capable of being very accurately rated.

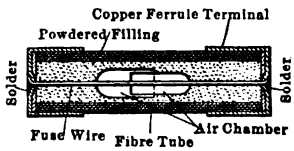

FIG. 11.—Typical enclosed-fuse construction.

**44. Renewable fuses** are those in which the fusible element can be replaced by the user. They are of the enclosed type, of standard Code dimensions and have recently been widely exploited, having met with considerable sale. Their use is not at present (1914) sanctioned by the Code, but it is not unlikely that certain forms of refillable fuse will be approved, under restricted conditions, for they possess decided economic advantages.

**45. Melting points of commercial fuse wire.** The following values are approximate, as the fusing points of metals depend on the proportion and kind of alloys used, kind and form of terminal, length of fuse and on other factors. (From Knox's "Electric Light Wiring;" table by Mr. Bathurst.)

| Nearest size A.W.G. | Diameter in thousandths of an inch | Fusing current in amperes |

**46. Cut-outs or fuse blocks** are devices whereby fuses can be inserted in an electrical circuit. Detailed specifications covering cut-outs for all approved currents and voltages are given by the Code. A combination of the Edison plug cut-out, and the ferule fuse and fuse-plug casing that can be used in connection with it, constitutes a most satisfactory fuse arrangement. However, this arrangement is limited to a capacity of 30 amp. at 125 volts. The Edison plug cut-out, which has a right-hand thread, is approved only for 125 volts; the Bryant Electric Co. makes a similar cut-out having a left-hand thread, which is approved, under certain conditions, for 250 volts. The right-hand thread cut-out is approved for only 125 volts because the Edison fuse-plug, which is not safe at a greater voltage, can be used in it. Cut-outs for open-link fuses consist merely of slate blocks, having mounted on them the necessary terminals.

**47. Diameters of Wires of Various Materials that will be Fused by a Current of a Given Strength**

## WIRING CALCULATIONS AND LAYOUTS

**48. The resistance** of a circular-mil-foot of commercial copper wire (a wire 1 ft. long and having cross-sectional area of 1 cir. mil) is usually quoted as from 10.6 to 10.8 ohms, at 75 deg. fahr. (24 deg. cent.). For wiring calculations 11 ohms per mil foot is a sufficiently accurate assumption. (See Sec. 4 for the Annealed Copper Standard.) On this basis the resistance of any commercial copper conductor is:

$$R = \frac{11 \times l}{\text{cir. mils}} \quad \text{(ohms)} \qquad (1)$$

Digitized by Google

Wherein, $R$ = resistance of conductor in ohms, $l$ = length of conductor in feet and *cir. mils* = the area of the conductor in circular mils. Also:

$$V = \frac{11 \times l \times I}{\text{cir. mils}} \quad \text{(volts)} \qquad (2)$$

where $V$ represents the drops in volts and $I$ the current in amps.

**49. Procedure in determining the size of conductor for a given circuit.** Practically all interior wiring problems involve the determination of the size of wire that will carry a certain current a given distance with a permissable drop in volts. The successive operations are:

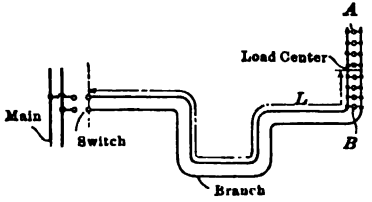

FIG. 12.—An example of load center.

(a) Determine the current, in amperes, that will flow in the circuit.

(b) Determine the distance from the point of assumed constant voltage to the load center of the circuit (Par **50**). This distance will be the actual circuit length if the load is concentrated at one end.

(c) Decide what voltage drop or loss is allowable (Par. **51**, **52** and **54**).

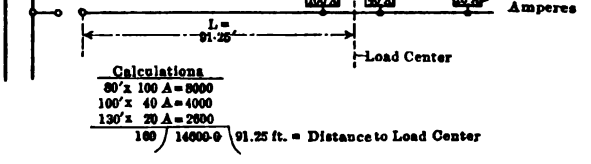
(d) Determine from the formulas the size of wire that will give the desired voltage drop.

(e) Check the derived wire size for current-carrying capacity, using the table in Par. **22**.

(f) Where economy of operation must be considered, check the cost of the energy dissipated in resistance; this should be kept within reasonable limits. See Par. **72** to and including **76**.

**50. The load center of a circuit** is that point at which it can be assumed that the total load is concentrated. The load center of a group of receivers, each of the same input and symmetrically arranged, will be at the middle of the group. (Fig. 12.)

To determine the load center of a group of receivers of unequal capacities



Calculations

80′ x 100 A = 8000
100′ x 40 A = 4000
130′ x 20 A = 2600

100 ) 14600.0 (91.25 ft. = Distance to Load Center

FIG. 13.—Determination of the load center of a circuit having receivers of unequal capacities, unsymmetrically located.

or unsymmetrically located, first multiply the normal current taken by each receiver by its distance from the starting point of the circuit; add all the products thus found, and divide this sum by the total current of the circuit. See Fig. 13. After some experience, one can by inspection determine the location of the load center with sufficient accuracy. Calculations for this factor are seldom made by experienced circuit designers.

**51. Allowable voltage drop in incandescent lighting circuits,** should not exceed 3 volts in 110-volt circuits and 6 volts in 220-volt circuits. Sometimes 4 or 5 volts drop is allowed in 110-volt circuits, but these are decidedly the upper limits and do not represent good practice. In per-

Digitized by Google

centages of the receiver voltage, a drop of from 1 to 3 per cent. is satisfactory and a 4.5 per cent. drop is the maximum. (See Par. **53.**) The above values represent the voltage drops from the source of assumed constant voltage to the lamp. Because of the extreme sensitiveness of the incandescent lamp to variations in voltage, the lamps may be subjected to overvoltages if the drops suggested above are exceeded—which will materially decrease their life; they may also be subjected to undervoltages when the circuit is loaded—which will decrease their brilliancy (Sec. 14). Some central-station companies specify that the total drop in 110-volt, interior-wiring circuits shall not exceed 1 volt.

**52. Allowable voltage drop in motor circuits.** A 5 per cent. drop is in accordance with excellent practice and a 10 per cent. drop or even a slightly greater one is often considered satisfactory. The drop should be calculated on the basis of full-load motor current. Where incandescent lamps are on the same circuits with motors the drops suggested in Par. **51** should not be exceeded. In designing motor circuits the question of conductor economy (Par. **73**) should be considered.

**53. Apportionment of voltage drop.** In circuit design it is necessary to apportion the total drop among the various component circuits—feeders, mains, sub-mains and branches. In incandescent lighting most of the drop is confined to the feeders because if there were excessive drop in the mains and branches, lamps located close together but served by different mains and branches might operate at decidedly different brilliancies.

With an isolated plant, that is where energy is generated on the premises, the drop may be apportioned exactly as indicated (Par. **54**). Where the premises is served by a central station (Par. **55**), the practice of the utility concern may allow 2 volts drop in its secondary mains and the service to the premises. In such a case, the total drop within the premises should not exceed 1 to 2 volts. Where a utility company is to give service, it should be consulted regarding its practice in this respect. Some central stations require that the voltage drop in interior wiring installations which they are to serve, shall not exceed a certain maximum. In any case, it is frequently the practice to allow one volt drop for the branches and to apportion the rest of the available drop to the main circuits and feeders.

**54. Typical Apportionment of Drop in 110-Volt Lighting Circuits**

| Part of circuit | Proportion | 4 volts total drop | | 3 volts total drop | |
|---|---|---|---|---|---|
| | | Actual drop, volts | Per cent. drop | Actual drop, volts | Per cent. drop |
| Branches | 1 volt | 1 | 0.91 | 1 | 0.91 |
| Mains | ⅓ remainder | 1 | 0.91 | ⅔ | 0.60 |
| Feeders | ⅔ remainder | 2 | 1.82 | 1⅓ | 1.21 |
| Total | | 4 | 3.64 | 3 | 2.72 |

**55. Apportionment of drop on 2,400-volt distribution systems** is often made under the assumption that the secondary voltage at the transformers remains practically constant. This will be found true in a well laid-out system, particularly if automatic feeder regulators are used.

**56. Apportionment of drop in motor circuits** is frequently made on the basis that 1 volt will be allowed in the branches, two-thirds of the remaining drop in the mains and one-third in the feeders. Most of the drop should be confined to the mains in order that a variation in the load on one motor of a group will affect the others as little as possible. Where motor circuits are fed by transformers, it is usually assumed that the voltage at the secondary side of the transformers remains practically constant, and therefore all of the allowable drop is apportioned to the secondary circuit. Where a group of motors is fed by a main circuit and branches, the drop in the branches, if they are not too long, is frequently 1 volt or less, under normal working conditions, because the insurance rules require that a branch conductor serving a motor be capable of safely carrying a current 25 per cent. greater than the normal full-load current of the motor.

Values below the heavy type exceed the maximum currents allowed for rubber-covered wire.

**58. Per cent. voltage drop** in practical wiring calculations is usually taken as a percentage of the receiver voltage. The voltage drop may be expressed in percentage of impressed voltage by the expression $p = V/(E+v)$, where $p$ is the per cent. drop, $V$ is the drop in volts and $E$ is the voltage at the receiver.

**59. Calculation of two-wire, direct-current circuits** is effected by means of the following formula,

$$\text{cir. mils} = \frac{22 \times I \times L}{V} \qquad (3)$$

wherein $V$ = drop in volts in the circuit, $I$ = current in amperes, $L$ = length one way or the single distance of the circuit in feet and *cir. mils* = the cross-sectional area of the conductor in circular mils.

**60. Calculations of three-wire, direct-current circuits** are made with Eq. 3, Par. **59.** In a balanced three-wire circuit no current flows in the neutral wire. In making wiring calculations in practice for three-wire circuits, it is assumed that the circuit is balanced. Ascertain the current that will flow in the outside wires of the three-wire circuit and then use Eq. 3, Par. **59.** The drop in voltage $V$ in the formula is the drop in both of the outside wires and is twice the drop to each receiver connected between the neutral and an outside wire. Obviously $V$ can be twice as great for a three-wire circuit as for the equivalent two-wire circuit. The neutral wire if unfused should be the same size as each of the outside wires in order to conform with *Code* requirements, but if properly fused it may be smaller.

**61. The method to be used in calculating an alternating-current circuit** is determined by the characteristics of the circuit under consideration. Where the circuit is short and the conductors will lie reasonably close together, the approximate methods suggested in following paragraphs can be used; these partially disregard the effects of power-factor and line reactance. The results obtained from these approximate formulas are usually subject to less error than other factors entering into the ordinary wiring calculation.

* NOTE:—The total length of wire is twice the single distance.

Digitized by Google

Where circuits are long and the conductors lie far apart, the results given by the approximate formulas should be checked by the Mershon-Diagram (Sec. 12) which considers the effects of power-factor and reactance Although the Mershon method is a trifle tedious, it will be found the quickest and the best when all things are considered. The use of the tables, that are frequently given for the determination of alternating-current conductors, will probably lead to inaccurate results, unless the user is familiar with their derivation. The effects of electrostatic capacity are inconsequental and need not be considered in ordinary interior wiring calculations.

**62. Line-reactance voltage drop** may be decreased either by diminishing the distance between the wires, or by dividing the copper into a greater number of circuits. Reactance is little affected by changing the size of the conductor. In interior wiring installations the conductors can be no nearer together than certain minimum distances specified by the *National Electrical Code*. Where installed in conduit the conductors are so close together that their reactance is practically negligible. All the wires of any alternating-current circuit (two wires for a single-phase circuit, three wires for a three-phase circuit or four wires for a two-phase circuit) should be carried as close together as feasible or, in a conduit installation, should all be in the same conduit, in accordance with the Code.

**63. Skin effect in interior wiring calculations** is ordinarily of little consequence, and need not be considered unless conductors are larger than 600,000 cir. mils in area. (Sec. 2 and Sec. 12.) As a general proposition conductors larger than 600,000 cir. mils are very difficult to handle, and, hence, are uneconomical to install; therefore, when greater area is required it is usual to arrange several conductors in parallel. Some engineers will use no conductor larger than 300,000 cir. mils in interior wiring. Fiber-cored cables (Par. **36** and **37**) should be used where conductors larger than 600,000 cir. mils are required.

**64. Calculation of alternating-current circuits of high power-factor,** such as are used for supplying incandescent lamps: in this case treat the circuits as if they were direct-current circuits, using Eq. 3, Par. **59**. This method is not strictly accurate but is sufficiently so for ordinary conditions. If the circuits are long and the wires are widely separated, the conductor sizes obtained as above should be checked by the Mershon-diagram (Sec. 12).

**65. To calculate single-phase, alternating-current circuits where line reactance may be neglected.** The following formulas can be safely used for the calculation of branch circuits and also of feeders and mains where the conductors are carried in conduit or are not very long. Where the circuits are of considerable length the result given by the formula should be checked with the Mershon diagram (Sec. 12). The current may be found from the expression:

$$I_1 = \frac{Kw. \times 1{,}000}{E \times p.f.} \text{ (amps.)} \qquad (4)$$

wherein, $I_1$ = current in amperes, $Kw.$ = kilowatts input of the load, $E$ = voltage of circuit and $p.f.$ = power-factor of load.

$$\text{cir. mils} = \frac{22 \times I_1 \times L}{V} \qquad (5)$$

Wherein, *cir. mils* = area of conductor; $I_1$ = current in amperes; $L$ = length (one way) of the circuit in feet and $V$ = volts drop allowable.

**66. Calculations of single-phase branches from three-phase circuits** are made in the same way as those for any other single-phase circuit (Par. **65**). However it must be remembered that if the branch is connected between one of the three phase wires and the neutral, the voltage impressed on the branch circuit will be 0.58 × the voltage across any two mains of the three-phase circuit

**67. To calculate two-phase, four-wire, circuits where line reactance can be neglected** the following formulas can be used. The limitations for this method are the same as those for single-phase circuits as outlined, Par. **65**. As with the single-phase equations (Eq. 4 and 5, Par. **65**), the Mershon diagram (Sec. 12) should be used for checking the conductors

Digitized by Google

for circuits of considerable length. Where the current is not known it can be found thus:

$$I_3 = \frac{Kw. \times 1{,}000}{E \times p.f. \times 2} = \frac{Kw. \times 500}{E \times p.f.} \quad \text{(amps.)} \quad (6)$$

Wherein, $I_3$ = current in amperes in each of the four wires of a balanced two-phase circuit, and the other symbols have the same meanings as in Par. **65**. The current being known:

$$\text{cir. mils} = \frac{22 \times I_3 \times L}{V} \quad (7)$$

Wherein all of the symbols have the same significance as outlined in this and preceding paragraphs. Use four wires of the same size.

**68. To calculate three-phase, three-wire, alternating-current circuits where line reactance can be neglected** the following formulas can be used. The limitations for this method are the same as those outlined for single-phase circuits in Par. **65**. As with the single-phase equations the Mershon diagram (Sec. 12), should be used for checking the results obtained for circuits of considerable length. Where the current is not known, it may be obtained from the expression:

$$I_3 = \frac{Kw. \times 1{,}000}{E \times p.f. \times 1.73} = \frac{Kw. \times 580}{E \times p.f.} \quad \text{(amps.)} \quad (8)$$

Wherein $I_3$ is the current in each of the three wires of a balanced three-phase, three-wire circuit, and where the other symbols have the same significance as in Par. **65**. When the current is known, then

$$\text{cir. mils} = \frac{11 \times I_3 \times L \times 1.73}{V} = \frac{19 \times I_3 \times L}{V}. \quad (9)$$

Wherein the notation is the same as outlined in this and preceding paragraphs.

**69. Calculation of single-phase circuits where line reactance must be considered.** The Mershon diagram (Sec. 12), is recommended for making such calculations. Other and apparently simpler methods are available, but all simple methods are inaccurate under certain conditions and are likely to get their user into trouble unless he is familiar with their derivation and limitations. The Mershon diagram does not offer a direct method of ascertaining drop; it is a "cut-and-try" method. Trials are made until a conductor size is found that will bring the drop within the specified limit. It is seldom that more than two trials are necessary. The method is a little tedious but not difficult, and will be found accurate under all ordinary conditions.

**70. To calculate a two-phase, four-wire, alternating-current circuit where line reactance must be considered,** use the Mershon diagram (Sec. 12), calculating a single-phase circuit (Par. **65**) which will transmit one-half the power at the same voltage. The two-phase transmission will require two such circuits.

**71. To calculate a three-phase, three-wire, alternating-current circuit where line reactance must be considered,** use the Mershon diagram (Sec. 12), calculating the conductor size for a single-phase circuit (Par. **65**), which will carry one-half of the load at the same voltage. The three-phase transmission will require three such conductors.

**72. Power loss in any circuit.** Assuming that 11 ohms is the resistance of a circular-mil-foot of copper conductor, the power loss in any conductor may be found thus:

$$P = \frac{11 \times I^2 \times l}{\text{cir. mils}} \quad \text{(watts)} \quad (10)$$

Wherein, $P$ = power lost in the conductor in watts, $I$ = the current in amperes in the conductor, $l$ = length of the conductor in feet and *cir. mils* = area of the conductor in circular mils.

For a two-wire circuit (direct-current or single-phase)

$$P = \frac{2 \times 11 \times I^2 \times L}{\text{cir. mils}} = \frac{22 \times I^2 \times L}{\text{cir. mils}} \quad \text{(watts)} \quad (11)$$

Digitized by Google

For a four-wire, two-phase circuit (assuming balanced currents)

$$P = \frac{4 \times 11 \times I^2 \times L}{\text{cir. mils}} = \frac{44 \times I^2 \times L}{\text{cir. mils}} \quad \text{(watts)} \qquad (12)$$

For a three-wire, three-phase circuit (assuming balanced currents)

$$P = \frac{3 \times 11 \times I^2 \times L}{\text{cir. mils}} = \frac{33 \times I^2 \times L}{\text{cir. mils}} \quad \text{(watts)} \qquad (13)$$

Wherein, $P$ = the power, in watts, lost in the circuit; $I$ = the current in amperes which flows in each of the wires of the circuit; $L$ = the length (one way) of the circuit; and *cir. mils* = cross-sectional area in circular mils of each of the wires. The above formulas can be used only when all of the wires of the line are of the same size.

**73. Conductor economy** in interior wiring installations always should be considered as a matter which is subordinate to the Code requirements. Obviously any conductor selected for a specific installation must fulfil the requirements of mechanical strength, ample carrying capacity (Par. **22** and **26**), and permissible voltage drop (Par. **51** and **52**). Frequently one of these three considerations will definitely determine the size of the conductor; however, a calculation of the resistance or $I^2R$ (power) loss (Par. **72**) may indicate that it will be desirable to use a larger size than is otherwise necessary.

**74. Annual charges** may be considered, in connection with the economical selection of a conductor size, to be made up of two items: (*a*)

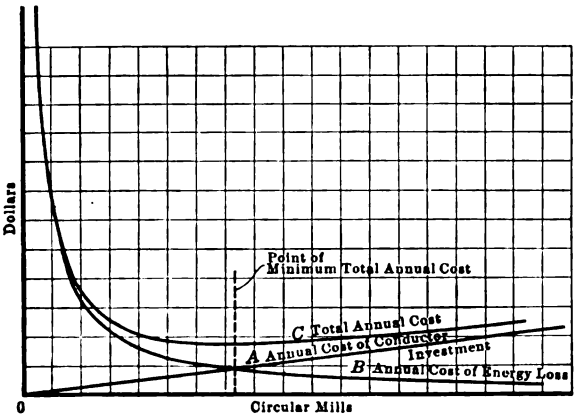

FIG. 14.—Graph illustrating Kelvin's law.

resistance-loss charges; (*b*) investment charges. Resistance-loss charges depend upon the resistance, the current and the unit cost of energy, and may be decreased by an increase of conductor size. This, however, calls for a greater investment with consequently larger investment charges. A conductor should be selected of such a size that the total annual charge (Sec. 25) will be a minimum.

In Fig. 14 the effect of a variation of conductor size on resistance-loss charge, investment charge, and total annual charge is shown graphically. The interest charges on the conductor increase directly with its cross-sectional area (curve *A*, Fig. 14). The resistance-loss charges decrease inversely as the cross-sectional area of the conductor (curve *B*, Fig. 14). The total annual charge (curve *C*, Fig. 14), the sum of curves *A* and *B*, is at its minimum value directly over the point where curves *A* and *B* intersect; that is, the conductor size that will have the least total annual cost is that

Digitized by Google

one for which the annual interest charge equals the annual resistance-loss charge. This proposition (Par. 75) has been demonstrated mathematically by Lord Kelvin.

**75. Kelvin's law** was deduced in 1881 by Sir William Thompson (Lord Kelvin). The original law was modified into the following more exact form by Gisbert Kapp: "*The most economical area of conductor is that for which the annual cost of energy wasted is equal to the interest on that portion of the capital outlay which can be considered proportional to the weight of copper used.*" On the basis of the above law it can be shown that:

$$\text{cir. mils} = 55{,}867 \times I \times \sqrt{\frac{C_e}{C_e \times A}} \qquad (14)$$

Wherein: *cir. mils* = area in circular mils of the most economical conductor; $I$ = the mean annual current (Par. 73). $C_e$ = cost of energy per kilowatt-hour, in dollars; $C_c$ = cost of copper in dollars per pound, installed; $A$ = annual charge in per cent. on the cost of the conductor. This can ordinarily be assumed as about 10 per cent. Note that neither the length nor the voltage of the circuit are factors in the equation.

The method involving Eq. 14 is best adapted to cases where the conductors are not insulated. It should be used always in connection with the method of Par. 76.

**76. Another determination of conductor size** may be followed in cases where the conductor cost will be large. This method is the preparation of a table showing energy costs and interest costs of an arbitrarily chosen length of conductor for a number of sizes.

| Size rubber-covered conductor..... | No. 4 wire | 250,000 c. m. | 300,000 c. m. | 400,000 c. m. | 500,000 c. m. | 600,000 c. m. |
|---|---|---|---|---|---|---|
| Cost of 400 ft. of conductor..... | $22.50 | $102.40 | $118.40 | $150.40 | $184.00 | $218.20 |
| Annual charges on above cost at 10%. | $2.25 | $10.24 | $11.84 | $15.04 | $18.40 | $21.82 |
| Cost of energy lost in conductor at 8 cents per kw-hr..... | $66.00 | $10.56 | $8.84 | $6.60 | $5.28 | $4.49 |
| Total annual cost of conductor..... | $68.25 | $20.80 | $20.68 | $21.64 | $23.68 | $26.31 |

The cost of unit length of conductors (preferably 1,000 ft. or 305 m.) may be obtained from the manufacturers' wire lists. Power loss may be calculated from Eq. 10 to 13, Par. 72.

By use of this table the situation may be made readily apparent, and a decision may be speedily reached. This method may be used as a check upon Eq. 14, Par. 75.

**77. In alternating-current systems of distribution** there are the two-wire and three-wire single-phase systems; the three-wire and the four-wire, two-phase systems, and the three-wire and four-wire, three-phase systems. All of these are usually fed from the secondaries of transformers located outside the building, either on poles or in subways.

**78. Single-phase, two-wire and three-wire systems** of distribution are similar to the direct-current systems, and the same precautions should be taken in the three-wire system to balance the loads on each side of the neutral.

**79. Factors for determining the mean annual current.** To ascertain the mean annual current for substitution in Eq. 14, Par. **75**, multiply the maximum current by the ratio applying to the conditions under consideration, given in the column headed "*Factor*" in the following table. The table is calculated on a basis of 24 hr. × 365 days = 8,760 hr. per year.

*Example.* If a maximum current of 1,000 amp. ($I$) flows $\frac{1}{4}$ of the time or 2,570 hr. per year and a current of 750 amp. ($\frac{3}{4}I$) flows $\frac{1}{4}$ of the time or 2,190 hr. per year the factor "0.944" would be used; that is, the value 0.944 × 1,000 amp. = 944 amp. would be the mean annual current for substitution in the equation of Par. **75** (Eq. 14).

| Proportion of time current is carried | Proportion of maximum current "$I$" carried | | | | Factor |
|---|---|---|---|---|---|
| | $\frac{1}{4}I$ | $\frac{1}{2}I$ | $\frac{3}{4}I$ | $I$ | |
| | 0 | 0 | 0 | 1 | 1.000 |
| | 0 | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | .944 |
| | 0 | $\frac{1}{4}$ | 0 | $\frac{1}{4}$ | .901 |
| | 0 | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | .844 |
| | 0 | 0 | 0 | $\frac{1}{4}$ | .866 |
| | $\frac{1}{4}$ | 0 | 0 | $\frac{1}{4}$ | .875 |
| | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | $\frac{1}{4}$ | .838 |
| | 0 | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | .820 |
| | $\frac{1}{4}$ | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | .810 |
| | 0 | $\frac{1}{4}$ | 0 | $\frac{1}{4}$ | .790 |
| | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | $\frac{1}{4}$ | .771 |
| | $\frac{1}{4}$ | $\frac{1}{4}$ | 0 | $\frac{1}{4}$ | .760 |
| | $\frac{1}{4}$ | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | .744 |
| | $\frac{1}{4}$ | 0 | 0 | $\frac{1}{4}$ | .729 |
| | 0 | $\frac{1}{4}$ | $\frac{1}{4}$ | $\frac{1}{4}$ | .718 |
| | 0 | 0 | 0 | $\frac{1}{4}$ | .707 |
| | $\frac{1}{4}$ | $\frac{1}{4}$ | $\frac{1}{4}$ | $\frac{1}{4}$ | .685 |

**80. Two-phase distribution** may be effected with four or with three wires. In the former case there is a pair of wires for each phase, while in the latter there is one wire for each phase and a common wire for both phases. The circuits must be balanced on either side, just as in the case of a three-wire, direct-current system, the only difference being that where three wires are used, the common wire is 1.4 times as large as either of the other two, since it must carry 1.4 times as much current. Motors are connected to both phases and employ all three or all four wires as the case may be. With four wires, the lamps are connected to each phase as though the supply were single-phase and care should be exercised to balance each phase as nearly as possible.

**81. The three-phase system** is usually employed where motors form a greater part of the load. Three conductors are necessary. Where lamps are required they are either balanced on the three-phases or connected between each main conductor and a common conductor of smaller size usually connected to the middle point of the star-connected secondary. The e.m.f. between any one of the three wires and the neutral is 0.577 (or 0.58) times the e.m.f. between the mains.

**82. Two-wire and three-wire systems.** Most interior wiring follows the two-wire system, the three-wire system being used principally for feeders and mains. With the direct-current three-wire system,

Digitized by Google

the neutral wire is frequently made of the same size as each of the two outer wires; sometimes it has a cross-section equal to twice that of one of the outer wires. The marked economy of copper ordinarily secured by the three-wire system is therefore not always realised in interior installations.

The three wires of the system are of the same size because if one of the outer fuses should blow, one side of the system would be loaded while the other side would have no current. In such a case the neutral would have to carry the same current as the outer wire, and were it smaller than the outer wire it would be overloaded. Where a grounded neutral has the same cross-section as either of the outer wires, the neutral fuse may be omitted; but not otherwise. By making the neutral of cross-section equal to the combined cross-sections of the outer wires, the system may be easily changed to a two-wire system. The latter plan is usually followed in large buildings, where a two-wire isolated plant is used and where the emergency connection with the light company's mains is three-wire.

**83. The load on a three-wire system must be balanced,** that is, the watts load should be approximately the same on either leg of the three-wire circuit. A variation of 10 or 15 per cent. may be permissible. Good balance is particularly important at maximum load. Unbalance causes unequal voltages, which is noticeable as producing a non-uniformity of illumination, and it may bring an overload on the conductors.

**84. Planning residence wiring.** Secure the floor plans or inspect the building. Decide where the meter is to be located; the point of entrance should be as close to the meter as possible. A good arrangement is to locate the service entrance (Par. 91) and the meter in the cellar. If the wires enter between the first and second floors, the meter may be installed in the rear hall. Ascertain how many lamp outlets there will be, their location, and the current required by each. Locate the distribution center at some central point convenient of access. Divide the outlets into groups which absorb less than 660 watts, each group being fed by one branch circuit from the distributing center. It is best to subdivide the outlets so that no branch circuit will have an initial load greater than 440 watts, which allows 220 watts for growth, so that the maximum of 660 watts, specified by the Code, shall not be exceeded.

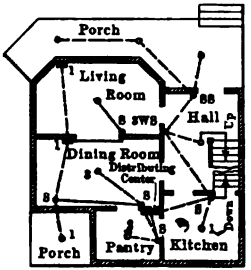

FIG. 15.—Example of a conduit-wiring lay-out in a residence.

Locate the switches and calculate the feeders required. Incandescent lamp branch circuits are usually of No. 14 wire unless they are longer than 100 ft. (30.5 *m*), in which case wire at least as large as No. 12 should be used; No. 14 is the smallest size permitted by the Code. Fig. 15 shows a typical lay-out for a small residence. Usually one panel or a group of cut-outs is sufficient for a residence. It is always preferable to group all cut-outs instead of locating them at random. In a small building, branch cut-outs or the panel box can often be set near the meter at the entrance or in the hall. In a two-story house they can be installed in the cellar stairway or in the rear hall, and in a three-story building they can be installed in the second floor hall. Where there are more than three stories, distributing centers can be located every second or third floor.

**85. Important features of large lay-outs.** There are five important points that must be considered in designing the wiring lay-out for a large building (Knox, "Electric Light Wiring"). They are: (*a*) control of groups of receivers (other than hall or night lights) from the main switchboard; (*b*) control of hall lights from the main switchboard; (*c*) maximum load that should be served by one feeder; (*d*) the best maximum limit for the size of the feeder conductors; (*e*) the proportion of the total voltage drop that can be allowed in feeders and mains.

**86. Wiring lay-out for a large building.** Make a sectional-elevation drawing of the structure and a floor plan of each floor. Indicate the receivers

Digitized by Google

(lamps and motors) on the plans and then so locate the panel boxes that no lighting branch circuit shall be much over 100 ft. (30.5 *m*) in length, or have a load much greater than 440 watts. Panel boxes should be so located that they are accessible and that the circuits can be readily run to them. Compute the load on each panel box and indicate it, at the box, on the drawing. Lay out the mains and feeders (see Fig. 16). First decide whether the hall or public lights will be controlled separately or with the private lights from the main switchboard, because this feature affects the arrangement of the feeders and possibly that of the mains. Next decide whether there should be a separate feeder to each floor or whether several floors or portions thereof will be served by one feeder. Where it is not necessary to control the loads on the different floors separately, and where the resulting conductor size will not be prohibitively large, the cheapest and probably the best arrangement is to serve several or possibly all floors with one feeder. Usually, the only limit to the number of floors that may be served with one feeder is the re-

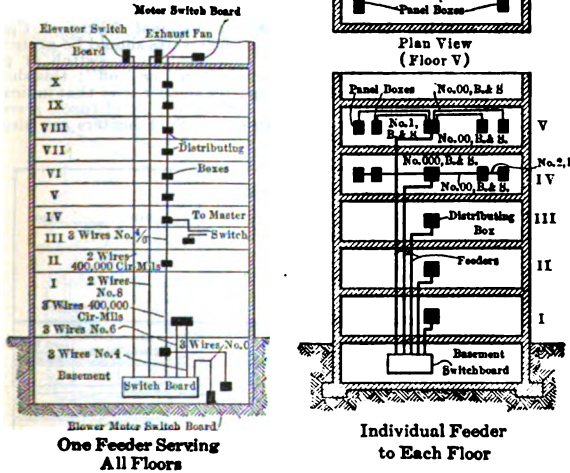

FIG. 16.—Wiring lay-outs in large buildings.

finement of control that is desired from the main switchboard. It is frequently necessary to make several tentative lay-outs and computations before the most desirable arrangement is found. Segregated motors and groups of motors, unless very small, should be served by independent feeders.

**87. Arrangement of feeders.** Solely on a basis of initial cost, it is usually cheaper to run a few large conductors than a number of small ones. It does not pay, however, to endeavor to install conductors larger than 1,000,000 cir. mils. When large capacity is necessary, use several conductors having the aggregate capacity required. For alternating currents, conductors larger than 700,000 cir. mils are not desirable because of skin effect. Often the space available for conductor runs necessitates small conductors (Par. **36** and **63**).

**88. Motor circuits** are subject to many special Code requirements. One unfamiliar with its rulings should refer to the Code before he attempts

Digitized by Google

to install motor wiring. The principal requirements follow: (*a*) motor circuits must be designed to carry a current at least 25 per cent. in excess of that for which the motor is rated; (*b*) where wires installed in accordance with this ruling would be overfused in order to provide for the starting current, the wires must be of such size as to be properly protected by these larger fuses; (*c*) where alternating-current motor leads are rubber insulated, the wire may be protected in accordance with the values for "Insulations other than Rubber" given in the Code table of safe current-carrying capacities (Par. **22**), except when circuit breakers equipped with time element devices are installed; (*d*) for determining the size of variable-speed, alternating-current motor leads, the current must be based on the percentage of the 30-min. rating indicated in the Code; (*e*) every motor installation (except for cranes) must be protected by a cut-out and must be controlled by a switch which plainly indicates whether it is on or off; (*f*) small motors may be grouped under the protection of a single set of fuses, provided their aggregate capacity does not exceed 6 amp.; (*g*) for motors of 0.25 h.p. or less on circuits at voltages of 300 or under, single-pole switches may be used. Switch and starting box should be so located that they are visible from the motor.

Motor manufacturers always furnish with each machine a diagram of connections and instructions for installation. These instructions should always be consulted.

**89. Electric heating-device circuits** (see *National Electrical Code*). A heater of a capacity greater than 6 amp., or 660 watts should be protected by an individual cut-out and should be controlled by a switch or plug connector which indicates whether the device is "on" or "off"; this should be visible from the heater. Heaters of a capacity smaller than that indicated above can be grouped under the protection of a single set of fuses, *provided* the capacity of the fuse does not exceed 10 amp. Such heaters can also be connected individually to lighting circuits.

FIG. 17.—Sheet for estimating cost of wiring installations (actual size should be about 18 in. wide by 12 in. long).

**Outlet plates** will be found convenient; each is provided with a receptacle, a switch and an indicating lamp socket. They are regularly manufactured for current capacities as high as 20 amp.; keyless brass sockets have a maximum rating of 6 amp. Ordinary pull-chain and key sockets have a maximum rating of 2.5 amp. Standard separable attachment plugs are approved for 660 watts at 250 volts or 10 amp. at 110 volts. Where ordinary key sockets are used for switching heating devices, they soon break down under the action of the arcs due to the relatively heavy currents. Snap or knife switches should always be used for heating devices. Specially constructed asbestos-covered, flexible cords are required for all devices absorbing more than 250 watts. In a first-class installation, it is always desirable to install separate circuits for the heating devices, extending from the entrance switch to the receivers. This permits individual metering and insures that the heavy currents drawn by the heating appliances will not interfere materially with the voltage regulation of the interior lighting circuits.

Digitized by Google

**90. Compilation of estimates.** Experience and a reliable note-book of labor costs applying to the community under consideration are the most valuable aids. Read the specifications or inspect the premises and make a wiring lay-out if there is none available. Make a list (Fig. 17) of all material required, following some definite system. A good method is to consider each distribution center—one at a time—and tabulate all the material required for the circuits feeding from it. Number or letter the distribution centers in accordance with a certain scheme and designate the branches with sub-notations. Indicate this notation on an estimating sheet similar to that of Fig. 17, in connection with your tabulation. Then proceed, tabulating panel-box, main, feeder and entrance material. After all is tabulated, the items can be totaled and these total values used for ordering material. Allow for some extra material for losses and breakages. Figure labor cost on a unit basis, that is, the cost of stringing wire being a certain value per 100 ft., the cost of erecting conduit being so much per unit length and so on through the entire list of materials. See cost data elsewhere for unit costs. A small job can be estimated with fair accuracy on a basis of so much per outlet, without the necessity of compiling a bill of materials.

## INSTALLATIONS

**91. Service entrances,** (Fig. 19). A cut-out and a fuse block should protect the switch. The wall should be bushed where the conductors pass through unless they are in conduit, and the tubes or conduit should be cemented in the wall. Tubes should slant outwardly and downwardly to

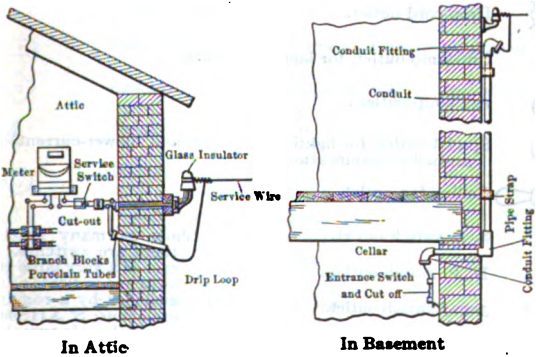

FIG. 18.—Service entrances.

prevent the entrance of moisture, and a drip loop should be formed of the service wires. The entrance switch should be so arranged that it will disconnect all of the equipment in the building except the main cut-out. Where conduit is used, the two or the three rubber-insulated wires should be carried in one conduit.

**92. Panel-box panels** may consist merely of porcelain cut-outs held to the back of the box with wood screws, or they may be more elaborate. The panel merely provides a convenient means of connecting the branch circuits to a main through fuses. Switches may be used in both main and branch circuits or they may be omitted entirely. Many satisfactory installations are in operation without switches, but switches are a great convenience for opening circuits when replacing fuses or for testing. In general, knife switches should not be used in branch circuits for the control of the lights, as they are frequently not of sufficiently strong construction to withstand permanently such service. Branch-lighting circuits should be controlled by either flush or surface snap switches mounted outside the panel box.

**94. Installation of watt-hour meters and maximum-demand meters.** (*Rules and Regulations of the Commonwealth Edison Co., Chicago*): Meter loops should be provided in the mains at an accessible point, and so arranged that the meter may be mounted with ordinary wood screws on the wall. A meter board must be provided of sufficient size to allow the installation of a watt-hour meter and maximum-demand meters. Two maximum-demand meters are installed on three-wire mains. Maximum-demand meters will not be installed on installations under 1 kw. Sufficient space must be provided about the meters to allow the removal of the case.

Meter boards should not be erected on a wall which is subject to any considerable vibration, or in places subject to excessive moisture or heat. A pressure-wire tap must be provided in all cases where all wires of the circuit are not looped out. On three-wire mains the pressure-wire tap must be made on the neutral wire. The general arrangements of meter loops should be such that a meter can be installed without crossing any wires, if possible. If this is impracticable, sufficient flexible tubing should be left on the wires to make possible an installation which will be in accordance with the wiring rules.

Meter loops should not be placed above 7 ft. from the floor, and should be as near the point of entrance of the service as possible. In office buildings meter loops should be located at a central point in meter closets or public corridors, and in apartment buildings in the basement of the building, so that meters may be installed and maintained without annoyance to tenants.

Meter loops must be located relative to fuses so that meters are protected by the fuses. They must never be placed between the service and the service switch. Generally speaking, not more than one meter installation will be provided for the same class of service in any one building.

Meter loops for service supplying temporary lighting or power to new buildings during construction must be located on adjoining premises. No three-wire meters larger than 200 amp. are used. Installations requiring meters of larger capacity will be provided with two meters, one on each side of the three-wire main; space should be allowed accordingly in arranging meter boards.

**95. Protection of watt-hour meters against unauthorized or malicious interference** is effected by means of seals and enclosing cabinets. See manufacturers' catalogues for further information, and "Metermen's Handbook," published by the National Electric Light Association.

**96. Panel boxes** are cabinets arranged to contain cut-outs and switches or protecting and controlling branch circuits where they are tapped from a main. It is desirable, in so far as possible, to group cut-outs in a wiring system; to this is due the popularity of panel boxes. Originally boxes were made without gutters; their disadvantage was that it was necessary to carry the entering wires for each branch circuit to a point opposite their proper cut-out. When the boxes are provided with gutters (now the usual form), conductors can enter the gutter at the most convenient point and can be carried in the gutter to a point opposite the cut-out. This arrangement results in material savings, particularly in conduit work.

Panel boxes may be either of the surface type, which extends wholly beyond the wall, or of the flush type, which does not extend beyond the wall. Surface-type boxes are used principally for factory wiring and for conduit installations in old buildings.

Panel boxes of sheet steel are suitable for factory work. The barriers in boxes with wooden gutters, are usually of slate or marble. The inside of a wooden box must be completely lined with a non-combustible insulating material. Slate or marble 0.25 in. (0.64 cm.), thick, or asbestos board 0.125 in. (0.32 cm.) thick may be used. Where iron conduit enters a box, the lining may be of either 0.25 in. (0.64 cm.) slate or marble, of 0.125 in. (0.32 cm.) asbestos board or of 0.062 in. (0.16 cm.) galvanized or painted sheet steel. Boxes should be painted inside and out. An asbestos or steel lining is preferable because slate or marble breaks easily. The door should close against a rabbet in order to be dust tight. Glass panels, 0.125 in. (0.32 cm.) thick, may be used in the doors. A 2-in. (5.08 cm.) space should be provided between the fuses and the door.

**97. Cost of interior wiring** (Lectures on Illuminating Engineering, Johns Hopkins University, October and November, 1910). Prices of labor and material differ in various localities and at different times. It is, there-

Digitized by Google

fore, difficult to state even approximately what the cost of distributing systems for lighting should be. In large cities, these variations are not extreme and it is possible to state the limits within which the cost, expressed in terms of the usual contractor's price per outlet, should lie. The figures given below apply to interior wiring of all classes, from the small residence to the large hotel or office building. They cover the portion of the work from the main source of supply, assumed to be at the building line. In case the building is lighted from its own plant these figures will apply to the portion of the installation lying between the lamp and the plant switchboard. No lamps, fixtures or reflectors are included in these prices:

Exposed wiring, $1.50 to $1.60 per outlet.

Wire in wooden moulding, $2 to $2.50 per outlet.

Concealed knob and tube wiring, $2.50 to $3 per outlet, with $1 added per switch outlet.

Wiring in iron conduit and in new buildings, $4.50 to $5 per outlet.

Wiring in iron conduits in concrete buildings, $5 to $6 per outlet.

In the above, switches and base-board plugs are considered as outlets when the iron box is included. If the switch and plate are also to be furnished, approximately $1 per outlet of this nature should be added. For the larger installations in modern buildings the price of $7 per outlet, including all wiring and feeders up to the lighting fixture, has been found to be a fairly close figure.

### 98. Cost of Residence Wiring

Cost for Different Numbers of Outlets, Single Floor Construction, Concealed Knob and Tube Work in Finished Buildings

*(Central Station Development Company, of Cleveland, Ohio)*

| No. | Cost | No. | Cost | No. | Cost | No. | Cost | No. | Cost |
|---|---|---|---|---|---|---|---|---|---|
| 5 | $15.85 | 17 | $37.40 | 29 | $57.20 | 41 | $77.82 | 53 | $100.82 |

| 16 | 35.75 | 28 | 55.55 | 40 | 75.90 | 52 | 99.00 | .... | ..... |

Add as per following for outlets under other than single floors and for hardware and drop cords.

*Under double flooring otherwise than hardwood. Second or third story.*

| | |
|---|---|
| Ceiling outlet | $1.00 extra. |
| Switch outlet for any center outlet | 1.00 extra. |

*Under hardwood flooring, single, double or triple. Second and third story.*

| | |
|---|---|
| Ceiling outlet | $3.00 extra. |
| One switch outlet for any center outlet | 3.00 extra. |
| Additional on same gang for same center outlet | 1.50 extra. |

*Switches, hardware and drop cords as per following:*

| | |
|---|---|
| Push-switches, each | $1.00 extra. |
| Push-3-way switches, per set of two switches | 2.75 extra. |
| Porcelain base switches, each | .35 extra. |
| Porcelain base Edison receptacles, each | .35 extra. |
| Baseboard flush plate receptacles, each | 1.15 extra. |
| Drop cord, key sockets each | .60 extra. |
| Drop cord, chain sockets, each | .75 extra. |

### 99. Cost of Double-braid, Rubber-insulated Wire in Conduit in Place

(Nelson S. Thompson, *Electrical World*, Sept. 9, 1911)

Costs do not include conduit

| Size, A.W.G. | Cost per 1,000 ft. | Size, A.W.G. and cir. mils | Cost per 1,000 ft. |
|---|---|---|---|
| Single conductors | | | |
| Solid | | Stranded | |
| 16 | $15.00 | 1 | $101.30 |
| 14 | 18.60 | 0 | 128.00 |
| 12 | 21.70 | 00 | 156.00 |
| 10 | 25.85 | 000 | 184.25 |
| Stranded | | 0000 | 217.00 |
| 8 | 35.40 | | |
| 6 | 48.25 | 250,000 | 275.00 |
| 4 | 62.65 | 300,000 | 327.00 |
| 3 | 75.25 | 400,000 | 405.00 |
| 2 | 82.00 | 500,000 | 500.00 |
| Duplex conductors | | | |
| 14 | $30.00 | 10 | $40.25 |
| 12 | 34.00 | 8 | 49.25 |

### 100. Cost of Conduit in Place (New Building)

| Size, in. | Cost per 100 ft. | Size, in. | Cost per 100 ft. |
|---|---|---|---|
| ½ | $8.50 | 1½ | $22.00 |
| ¾ | 10.25 | 2 | 30.60 |
| 1 | 13.75 | 2½ | 47.00 |
| 1¼ | 18.25 | 3 | 60.00 |

### 101. Cost of Conduit Elbows in Place (New Building)

| | |
|---|---|
| 2 -in. size | $1.00 each |
| 2½-in. size | 1.25 each |
| 3 -in. size | 4.00 each |
| 4 -in. size | 10.00 each |

**102. Estimating costs of conduit installations.** The Treasury Department of the United States uses the following methods and values for computing the costs of conduit wiring in federal buildings. (Nelson S. Thompson, *Electrical World*, Sept. 9, 1911.) The figures are for high-grade work in fire-proof buildings. The material is taken off accurately from the drawings. The total amounts of conduit and wire are the lengths scaled from the plan plus the following: Number of ceiling outlets×2 ft.; number of bracket outlets×10 ft.; number of switch outlets×10 ft.; number of baseboard outlets×4 ft.; number of two-gang switches×15 ft., and number of three-gang switches×20 ft. Table in Par. **100** shows the cost of conduit in place. For the cost of underground service connections in place and for work in old buildings where walls and ceilings are cut and where plaster must be replaced, 50 per cent. should be added to the tabulated values.

The cost of all kinds of outlet boxes in place is 25 cents each in new buildings and is 50 cents in old buildings where plaster must be repaired The cost of large junction boxes in place is 5 cents per lb. Plug receptacles in place cost $1.30 each. Single pole snap switches in place cost $1 each. Fixture studs cost 5 cents each in place; outlet bushings 5 cents each in place; locknuts 1 cent each in place. One should estimate 3 bushings and 3 lock-nuts per outlet.

The average total cost of lighting systems complete in place in eastern sections of the country is about $12 per outlet; in the West and South the cost will be about $15 per outlet, and in the extreme West the cost per outlet

Digitized by Google

will be $20. The number of outlets upon which these figures are based does not include switch outlets, but only the actual lamp outlets. In old buildings the cost of the conduit and wiring work is $20 to $25 per outlet and $30 in the extreme West.

## PROTECTION

**103. General principles regarding the use of fuses.** Fuses or some other form of overload protection should be used where the protection of conductors or appliances against overload is desirable. The *National Electrical Code* specifies in detail as to their application. Constant-potential generators should be protected against overload by fuses or their equivalent. Single-pole protection is acceptable under certain conditions for direct-current generators. Fuses should be placed at every point where a change is made in the size of wire, unless the fuse on the larger wire is of such capacity that it will protect the smaller one.

Fuses should be inserted in all service wires, and should be located in an accessible place as near the entrance to the building as possible. For three-wire systems, the neutral wire need not be fused, provided the neutral wire has a carrying capacity equivalent to that of the larger of the outside wires, and if the neutral is grounded. No group of small receivers, whether motors, incandescent lamps or heating appliances, requiring more than 660 watts should depend on one cut-out. The rated capacity of a fuse protecting any wire should not exceed the safe carrying capacity of that wire as specified in Par. 23. Each wire for a motor circuit, except at a switchboard, should be protected by a fuse whether or not circuit-breakers are used, except where the motor is of such large capacity that fuse protection cannot be obtained, in which case it is only possible to use circuit-breakers.

**104. Fuses vs. circuit-breaker.** Fuses possess a time element of operation (see Fig. 20) which circuit-breakers do not have unless specially designed therefor. Due to this property, fuses delay the opening of an over-loaded circuit, where the operation would be practically instantaneous with circuit-breakers; fuses, then, may be preferable for motor circuits and for circuits that are subject to very brief overloads, especially where expert supervision of electrical apparatus is maintained, as in large mills and factories. Where there are many fuse replacements, the cost of fuse renewals is considerable.

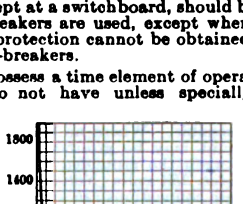

FIG. 20.—Typical performance curve of a 400-ampere, 500-volt, National Electrical Code standard fuse.

Circuit-breakers can be reset in less time and with less trouble than is required to replace blown fuses, and no spare parts are required. Circuit-breakers may, therefore, be preferable where the time saved by their use is an important consideration. The first cost of the circuit-breaker equipment is more than the cost of fuse equipment, but under severe service the circuit-breakers will prove less expensive in the end.

**105. Grounding the neutral of three-wire circuits.** It is important that the path through the neutral remain intact. Grounding promotes this condition, and the Code authorizes it, provided that: (a) the neutral is thoroughly grounded at the central station; (b) in underground systems the neutral is grounded at each distributing-box; and (c) in overhead systems, every 500 ft. Normally in a well-designed system, the neutral carries a minimum of current. Frequently, in underground systems, a bare copper wire drawn in the ducts constitutes the neutral. If the neutral becomes open, the pressure normally existing between the outer wires may be imposed on the equipment connected between the neutral and an outer wire; under these conditions the equipment may be ruined and a fire may result, since the voltage thus imposed will be twice that for which the equipment was designed.

**106. Alternating-current, low-voltage, secondary circuits should be grounded.** This is the recommendation of the *National Electrical Code* and is the practice of progressive central-station companies. Ground-

Digitized by Google

ing prevents accidents to persons and damage, by fire, to property. If some point of a low-voltage secondary circuit is grounded, no point of the circuit can rise above its normal potential (except under unusual conditions) in case of a breakdown between primary and secondary windings of the transformer, or of other accidental connection between the primary and secondary circuits. See The *National Electrical Code* for further information regarding grounding.

The ground connection should be made at a neutral point or wire if one is

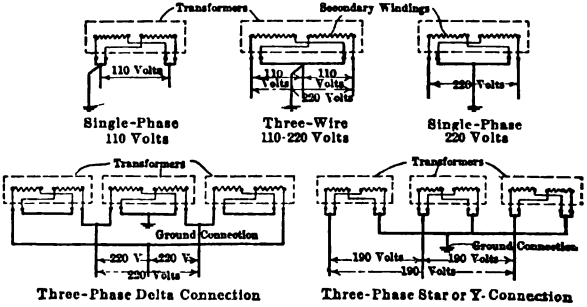

FIG. 21.—Ground connections to secondaries of commercial transformers.

accessible. Where no neutral point is accessible, one side of the secondary circuit may be grounded, provided the maximum difference of potential between the grounded point and any other point in the circuit does not exceed 250 volts (*National Electrical Code*). Fig. 21 illustrates how some of these connections are arranged with commercial transformers. The neutral point of each transformer feeding a two-phase, four-wire secondary, should be grounded, unless the motors taking energy from the secondary have

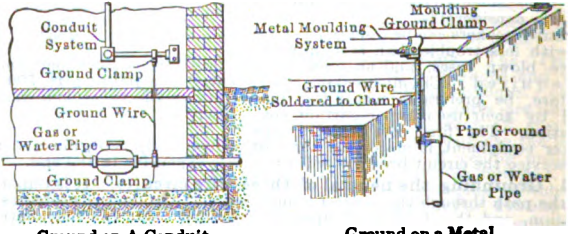

FIG. 22.—Methods of grounding.

interconnected windings. Where they are interconnected, the center or neutral point of only one transformer is grounded. No primary windings are shown in the illustration and the secondary winding of each transformer is shown divided into two sections, as in commercial transformers.

**107. All metal conduit and metal-moulding systems must be grounded** (see Fig. 22), by attaching an approved clamp (there are many on the market) to a conduit or moulding of the system and connecting it with a ground wire to another clamp attached to a water or gas pipe on the

Digitized by Google

street side of the meter. The wire must be soldered in the clamps. All parts of the conduit or moulding system must be in good electrical contact. In an ungrounded system of conduit, "sneak" currents are possible. These leak from one wire to the conduit through an abrasion of insulation and reach the other side of the line through another ground. The resistance of the path may be sufficient to hold the "sneak" currents below the line fuse capacity, and yet these currents may be sufficient to start a fire. Grounding the conduit also eliminates the possibility of electrical shock to persons coming in contact with the conduit. In combination fixtures the gas pipe should be in thorough electrical contact with the conduit or moulding system at each outlet box.

Wire for grounding conduit or moulding must be of copper, at least No. 10 B. & S. gage, where the largest wire contained in system is not greater than No. 0 B. & S. gage. It need not be greater than No. 4 B. & S. gage where the largest wire contained in conduit is greater than No. 0 B. & S. gage. The wire must be protected from mechanical injury.

## MISCELLANEOUS

**108. Wire for bell signal work** in dry places is usually No. 18 copper, double-cotton-covered and paraffined. Where more than two or three bells or similar devices are connected to the circuit, or where the circuits are long, No. 16 wire should be used. No. 14 is frequently used for battery wires. Rubber-covered, twisted-pair wires, like those used for interior telephone wiring, can often be used to advantage in damp places or where the circuits are exposed. No. 20 wire, although sometimes used, is too small for reliable work. Annunciator and twisted-pair wire is made with insulating coverings of different colors, so one can be selected that will match the surroundings, and be inconspicuous. Cables of annunciator wire, which can be obtained with practically any number of conductors from 2 up to 200, are very convenient and economical for large installations. In perfectly dry locations, a cable having a paraffined, braided-cotton covering can be used, but if it is to be exposed to dampness a lead-covered cable should be installed. By having the cable conductors covered with braids of different colors, the conductors can be readily identified. A kind of weather-proof wire called "damp-proof," is quite satisfactory for exposed wiring in damp places. It is more expensive than annunciator wire, but it has a better appearance when installed. See the *National Electrical Code*, the "Telephone" section in this book and the Western Electric Co. catalogue for further information.

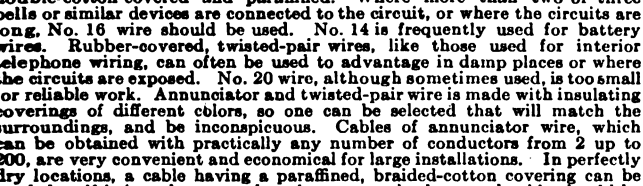

FIG. 23.—Burglar-alarm system.

**109. Telephone wiring** may follow the practice of the central-exchange or the intercommunicating system. In the former, single pairs of wires radiate from a switchboard to all stations. In an intercommunicating system, a cable of twisted pairs of insulated wires extends continuously through all the stations. This cable must contain at least one more wire than there are stations (Sec. 21). Conductors of No. 25 A.W.G. have been used; also No. 22 and No. 19, according to transmission requirements (Sec. 21).

**110. Fire alarm wiring** should be very carefully and substantially installed. As a general proposition, the wires should be heavier than would be used in ordinary signal practice; nothing smaller than No. 14 should be used indoors and nothing smaller than No. 8 out of doors. For interior lines, rubber-insulated copper should be used, while for outside construction, weather-

Digitized by Google

proof copper wire is satisfactory. The simplest possible arrangement consists of an alarm gong connected to a battery and a group of single-pole switches that are normally open. In case of fire one of the switches is closed, and the alarm rings until it is stopped.

**Burglar-alarm systems** (see Fig. 23) may be divided into two general

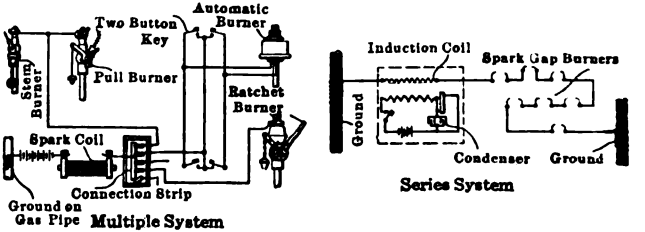

FIG. 24.—Electric gas-lighting circuits.

classes: the open-circuit system, in which the circuits for the protected doors and windows are normally open, and when a circuit is closed by the opening of a door or window, an alarm is sounded; the closed-circuit system in which the alarm is sounded by the opening of a circuit normally closed. Open-circuit systems are simpler, but closed-circuit systems are more

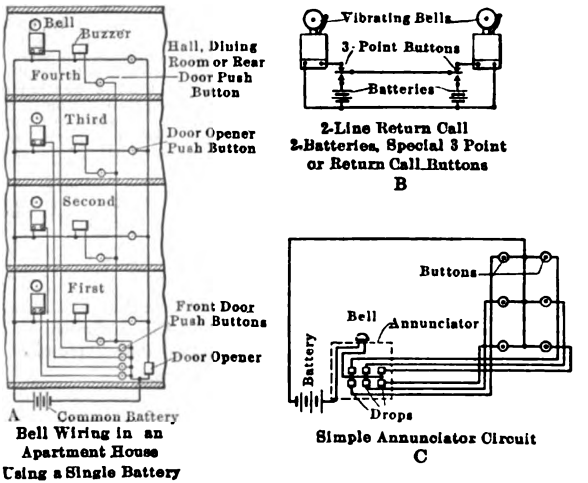

FIG. 25.—Typical electric bell and annunciator circuits.

sensitive and provide better protection; in the latter if the circuit is opened at *any point*, the alarm is sounded. Annunciators and burglar alarm fittings to be used in connection with either system are obtainable for the protection of doors, windows, shades, transoms and locks. See the "American Electricians' Handbook."

Digitized by Google

**111. Electric gas-lighting wiring** may follow the multiple system or the series system (Fig. 24). In the multiple system a spark is made by the breaking of an electrical circuit containing a reactance coil. One side of the circuit is usually grounded on the gas pipe. Electrically equipped burners of many types are obtainable. Certain spark coils are equipped with relays which sound an alarm if the system becomes short-circuited. Open circuit cells are used, a battery of 6 Leclanché cells in combination with a spark coil being usually sufficient.

In the series system, a spark gap is installed at each burner. The spark may be fed from induction coils or from frictional or static machines. The series system may be best adapted to large auditoriums, where many lamps are used in groups. It is now seldom used because such places are almost invariably lighted with electricity. See the "American Electricians' Handbook."

**112. Electric bell and annunciator wiring.** The possibilities for different circuit combinations are almost numberless. Those shown in Fig. 25 are typical. Two ordinary vibrating bells will not work well together in series; so when it is necessary to connect two bells in series, one should be a single-stroke bell. A multiple arrangement is preferable. The best arrangement of battery cells may be determined by trial. An ordinary bell requires about 0.1 amp. for its operation. Return call-bell circuits (*B*, Fig. 25) are so arranged that, when a station is signalled, the party called can respond by pressing his button. Ground return circuits may be used but are undesirable. Continuous-ringing bells are so arranged that, when the button is pressed, the bell continues to ring until reset. For elevator annunciators a cable is used, having as many conductors as there are buttons and one additional battery wire. If two annunciators are to operate simultaneously, their drops should be connected in series. See the "American Electricians' Handbook" for further information.

# ILLUMINATION

## PRODUCTION OF LIGHT

### GENERAL THEORY OF LIGHT PRODUCTION

**1. Light may be defined** as radiant energy of those wave lengths to which the human eye is sensitive. Energy, of a nature with which the problem of light production is concerned, is radiated through a number of octaves forming the spectrum. The human eye is stimulated to vision only by that radiation which is between wave lengths 0.76$\mu$ and 0.38$\mu$, or one octave. ($\mu = 0.001$ mm.) The limits of visibility are not definitely fixed, but those given are reasonably typical.

**2. Incandescence** is that process of light production, classed as temperature radiation, in which a body, usually a solid or a liquid, produces light without altering its nature in the process. The spectrum of such radiation usually is continuous.

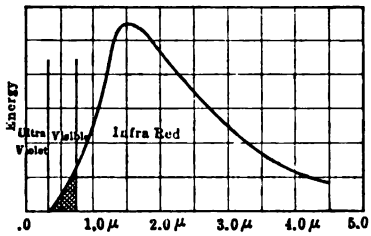

FIG. 1.—Radiation from "black body."

**3. Pure temperature radiation** is not completely realised in ordinary light sources, but it characterises the theoretical "**black body**" which radiates the maximum possible energy at all wave lengths (Fig. 1). According to the **Stefan-Boltzmann law**, the total radiation of such a body is proportional to the fourth power of its absolute temperature

$$R = a\,(t+273)^4 \qquad (1)$$

$t$ is the temperature in deg. cent. $a$ is a measurable constant.

**4. Wein's displacement law*** shows that the relation between the wave length of maximum radiation intensity and the absolute temperature is a constant, which, for a black body has been determined to be 2940.

$$\lambda_{max} = \frac{2940}{T} \qquad (2)$$

$\lambda$ in microns. (micron is 0.001 mm.)

Wein has shown further that the intensity at wave length of maximum black-body radiation varies as the fifth power of the absolute temperature. The intensity of radiation at any wave length is obtained from the **Planck formula** as follows:

$$J = \frac{C_1}{\lambda^5\left(e^{\frac{C_2}{\lambda\theta}} - 1\right)} \qquad (3)$$

* For exposition of derivation of equations and discussion of subject, see Drysdale, "The Production and Utilization of Light." *The Illuminating Engineer*, London, 1909, p. 230 and Bulletin, Bureau of Standards, Vol. VII, p. 395.

Digitized by Google

where
$J$ = radiation intensity; $C$ = constants;
$\theta$ = temperature in deg. abs. and $e$ = logarithmic base

Curves of radiation from a black body, computed according to this law, appear in Fig. 2.

**5. Perfect black-body or temperature radiation** is not found in artificial illuminants. Among incandescent electric lamps it is approached—most closely by "untreated" carbon-filament lamps (10-watt, 110-volt and 50-watt, 220-volt types)—in lesser degrees by "treated"-carbon, "metallised"-carbon and tungsten-filament lamps. The carbon filaments depart from a black body less than does platinum, for which a displacement-law constant (Par. 4) of 2630 has been found.

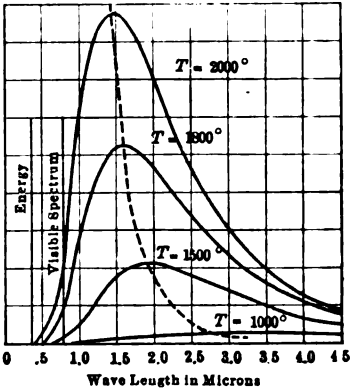

FIG. 2.—Black-body radiation at several temperatures.

**6. Gray-body radiation** is distributed throughout the spectrum in the same proportions as black-body radiation, but is everywhere less intense. It differs from black-body radiation in quantity, not in quality.

**7. Selective radiation** is distributed differently throughout the spectrum and does not obey the laws of black-body radiation. If it is relatively strong between the limiting wave lengths of visibility, particularly if near the middle of the visibility range, the body produces more light, and the selectivity is favorable. Curves of black-body, gray-body and of one kind of selective radiation are given in Fig. 3.

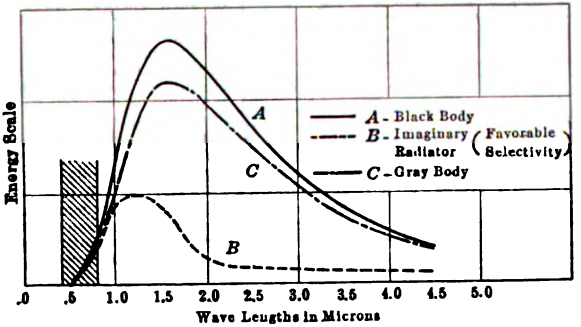

FIG. 3.—Three kinds of radiation.

**8. Luminescence** is that form of light production in which the radiating body (usually a gas or vapor) changes its nature in the process. Such radiation usually is characterised by a line spectrum. Luminescence embraces all forms of light production other than incandescence. In electric lighting it is the process by which light is obtained from gases or vapors. The mercury-vapor and the metallic-electrode (magnetite and

Digitized by Google

metallic-flame) arc-lamps are examples of this method of light production. Radiation by luminescence may be strongly localized in a few lines of the spectrum, as in the mercury-vapor lamp (Fig. 4), or may be distributed so generally as to approximate, for many illuminating purposes, a continuous spectrum. It usually manifests more pronounced selectivity than is found among incandescent solids. Unlike temperature radiation, luminescence is characterised by fixed spectral distribution of radiation, this being independent of the intensity of the excitation.*

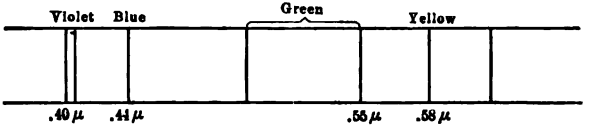

FIG. 4.—Spectrum of mercury arc.

**9. Luminous efficiency.** The problem of light production is in part that of radiating as much as possible of the energy within limits of visibility represented by wave lengths of 0.76μ to 0.38μ. There are two expressions for the efficiency with which this is accomplished. These are "**total luminous efficiency**" (radiation efficiency) or the ratio of energy radiated within the visibility range, to that expended in the illuminant; and "**radiant luminous efficiency,**" or the ratio of energy in the visibility range to the total radiated energy.† For an incandescent electric lamp in which most of the applied energy is converted into radiant energy, the two luminous efficiencies do not differ widely. For a multiple arc lamp in which a material part of the energy is not applied at the arc, the difference is large. Both total and radiant luminous efficiencies are of interest chiefly to the physicist, neither affording a real measure of illuminating efficiency. Both deal exclusively with the total energy radiated between visibility limits, ignoring the distribution of such energy. As a given energy radiated at 0.55μ will produce say ten times as great an illuminating effect as if radiated at 0.65μ or 0.45μ, consideration of the distribution of radiation is essential from the illuminating standpoint.

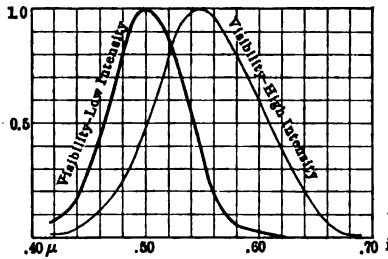

FIG. 5.—Luminosity curves for normal human eye.

**10. "Luminosity curves"** for the normal human eye stimulated by radiation of uniform intensity throughout the visible spectrum are given in Fig. 5.

**11. The illuminating power of radiation** of any wave length is proportional to the product of the energy and the coefficient of eye sensibility. The problem of efficient light production is largely that of radiating as much as possible of the energy at wave lengths to which the eye is most sensitive. This may be taken as 0.55μ although the wave length of maximum sensibility varies with the intensity (Fig. 5), being shifted toward the shorter wave lengths as the intensity of the stimulus is reduced. Radiation would have the highest possible light value if it were concentrated at or near 0.55μ.

**12. The "mechanical equivalent of light"** is the ratio of radiated energy within given wave-length limits, to the illuminating power of such energy. It may be expressed in watts-per-candle or watts-per-lumen.

* Nichols and Merritt. *Physical Review*, Vol. XIX, p. 18.

† "Luminous Efficiency," *Transactions* Illuminating Engineering Society, Vol. V, p. 113.

Digitized by Google

There can be no one value for the mechanical equivalent of light applicable to all illuminants, if all energy in the visible range is included, because of the variation of eye sensibility with wave length. If, however, a narrow band of spectral radiation be separated and studied, a definite and reproducible ratio between energy and light value may be obtained. And if this band be selected from the part of the spectrum where the light value is highest (say 0.55$\mu$), the minimum possible mechanical equivalent of light will result. Ives,* having compared with his own the experimental data and calculations of other investigators, has assigned the value of 0.02 watt per mean spherical candle, or 0.0016 watt per lumen, as the most probable mechanical equivalent of yellow-green light, to which the eye is most sensitive.

With this criterion of light producing efficiency available for the highest point of the ocular-luminosity curve (Fig. 5), a scale of ordinates for that curve is established, and the curve yields the sensibility coefficient for each wave length. This applied to the radiation curve (Fig. 2), gives a curve of visibility, from which the total illuminating power may be integrated. The value so obtained should equal the candle-power or the lumens as measured by a photometer. The value of mean spherical candle-power per watt or of total lumens per watt, when stated in terms of the most efficient light per watt, yields the "reduced luminous efficiency." (Drysdale's terminology.) The table of Par. 13 shows data of this kind based upon Ives' compilation.

**13. Efficiency of light production**

(Electrical World—Vol. LVII, p. 1566)

| | Watts per mean sph. c-p. | Per watt | | Reduced luminous efficiencies (based on radiated energy) |
|---|---|---|---|---|
| | | Mean sph. c-p. | Lumens | |
| | | | | Per cent. |
| Yellow-green 0.55$\mu$..... | 0.02 | 65 | 800 | 100 |
| Firefly..... | ..... | ..... | ..... | 96 |
| Black-body, about 5,000 deg. abs. | ..... | 10 | 125 | 15 |
| Ditto, excluding energy outside limits 0.76$\mu$ to 0.38$\mu$. | ..... | 22 | 274 | 34 |
| Ditto, excluding energy outside limits 0.70$\mu$ to 0.40$\mu$. | ..... | 26 | 330 | 41 |

**14. In "reduced luminous efficiency"** (see Par. **12**) we have a very practical measure of efficiency of light production, because for any illuminant the ordinary commercial rating is directly comparable with the standards of highest possible efficiency. With this system of rating, everything depends upon the correctness of the standard of light production. But it may be noted that all artificial illuminants are so low in efficiency that a considerable error in fixing the standard would not alter materially the conclusions as to the inefficiency of illuminants. Standards for this purpose appear in Par. **16**.

**15. White-light efficiency.** "Reduced luminous efficiency" (Par. **14**) is the light flux per watt in per cent. of the yellow-green flux obtained from 1 watt radiated at 0.55$\mu$. Such yellow-green light would be undesirable for most illuminating purposes. The generally accepted ideal is white light. Ives† has proposed the radiation between 0.70$\mu$ and 0.40$\mu$ from a black body at 5,000 deg. abs. as a standard of white light, and has assigned 330 lumens per watt as the most probable value of the most efficient white light obtainable. This is a satisfactory criterion for illuminating purposes. Ives‡ also has studied the spectrophotometric curves of some of the common incandescent sources to ascertain what proportion of their light is available to

*Luminous Efficiency, *Trans.* I. E. S., Vol. V, p. 113.
† *Electrical World*, Vol. LVII, 1909, p. 1566.
‡ Bulletin, Bureau of Standards, Vol. VI, p. 238.

Digitized by Google

form white light. Assuming colored absorbing screens of exactly the desired values to transmit with minimum loss that part of the radiation of each wave length necessary to produce white light, he has shown the "white-light" or "daylight efficiency" of each source. These values, recently revised, appear in Par. 17.

**16. Light-producing efficiencies of certain electric illuminants**

| Light source | Mean spherical c-p. per watt | Lumens per watt | Reduced luminous efficiency |
|---|---|---|---|
| | | | Per cent. |
| Radiation at 0.55$\mu$ | 65 | 800 | 100 |
| Radiation from black body at 5,000 deg. abs.—excluding that outside 0.7$\mu$ and 0.4$\mu$. | 26 | 330 | 41 |
| Masda vacuum lamp—1.0 w.p.c. | 0.78 | 9.8 | 1.2 |
| Masda gas-filled lamp—large size | 1.8 | 22.5 | 2.8 |
| Magnetite-arc—4.0 amp. | 0.85 | 10.7 | 1.3 |
| Flame-arc—10-amp.—white-light carbon—approximate. | 1.4 | 17.6 | 2.2 |

**17. White-light efficiencies of incandescent lamps**

| Lamp | Watts per mean spherical c-p. | Lumens per watt | White-light efficiency | White-light lumens per watt | Per cent. of most efficient white-light (330 lumens per watt) |
|---|---|---|---|---|---|
| | | | Per cent. | | Per cent. |
| Carbon | 4.85 | 2.59 | 7.6 | 0.195 | 0.06 |
| Carbon | 3.75 | 3.35 | 8.6 | 0.29 | 0.09 |
| Gem | 3.10 | 4.05 | 10.0 | 0.405 | 0.12 |
| Tantalum | 2.60 | 4.83 | 10.0 | 0.485 | 0.15 |
| Tungsten | 1.56 | 8.05 | 13.7 | 1.10 | 0.33 |

**18. Physical and physiological aspects of white light.** Both the standard of white-light efficiency and the values shown for common illuminants are values for continuous-spectrum light from incandescent sources. That is to say, this method provides only for true white light, which is satisfactory physically as well as physiologically. Light produced by luminescence, which has a line spectrum, may be accepted as white in a physiological sense, but may fail to serve for certain illuminating purposes where true white light is required. It is doubtful if such light should be compared with true white light upon the same terms. At any rate notation should always be made of the peculiarities of spectral distribution of such light.

## CHARACTERISTICS OF ELECTRIC LAMPS

### INCANDESCENT LAMPS

**19. Incandescent electric or glow lamps produce light by process of** incandescent or temperature radiation. Hyde* has estimated that if operated at the same true temperature, the several filaments, due to **favorable selectivity**, would be more efficient than untreated carbon, which is least selective. Relatively these efficiencies are as follows: untreated carbon, 100 per cent.; tantalum, 110 to 112 per cent.; tungsten, 125 to 130 per cent.

**20. The resistance characteristics** of the more common types are shown in Fig. 6,† where 100 per cent. corresponds with the standard rated efficiency.

* Lectures on Illuminating Engineering, I. E. S.—Johns Hopkins University.

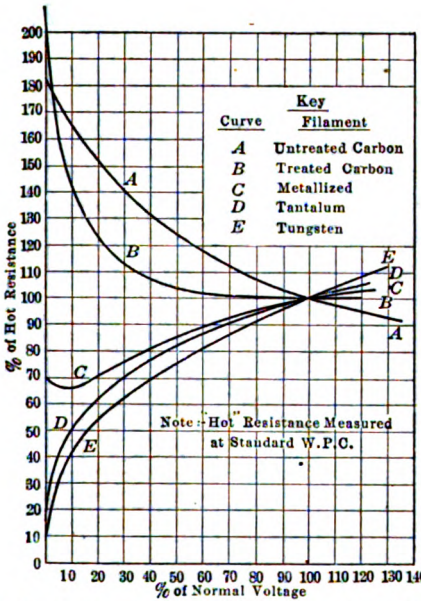

FIG. 6.—Resistance characteristics of incandescent lamps.

**21. Resistance of filament lamps**

| Lamp | Cold resistance | Resistance at standard efficiency |
|---|---|---|
| 20-watt untreated-filament | 1062 ohms | 582 ohms |
| 60-watt treated-carbon | 459 ohms | 225 ohms |
| 60-watt metallized-carbon | 156 ohms | 222 ohms |
| 50-watt tantalum | 44 ohms | 262 ohms |
| 60-watt tungsten | 16.5 ohms | 206 ohms |

**22. The physical characteristics** of these lamps (Par. **20**) are shown in Fig. 7, 100 per cent. volts corresponding with rated efficiency. Throughout a range of a few volts above and below normal, these relations may be expressed as parabolic equations.

$$\frac{V_1}{V_2} = \left(\frac{e_1}{e_2}\right)^k \qquad (4)$$

The exponents* are not determined beyond question, particularly for tungsten filament (Mazda) lamps, where improvements in manufacture are being made so rapidly that statistics for the final establishment of these values are not available for lamps of latest manufacture. Best known values for the exponents are given in Par. **23**, and are reasonably accurate throughout a working range of voltage variation. Par. **24** shows corresponding exponents for the variation in life with change in watts per candle.

**26. Commercial ratings**
(November, 1914)

| Filament | Initial rated values: Watts | Mean horizontal c-p. | Total lumens | Commercial rating-watts per mean horizontal c-p. | Specific consumption: Watts per mean spherical c-p. | Specific output: Lumens per watt |
|---|---|---|---|---|---|---|
| 100 to 130 volts | | | | | | |
| Carbon—untreated..... | 10 | 2.0 | 21.2 | 5.0 | 5.88 | 2.12 |
| Carbon—treated..... | 50 | 16.8 | 174.5 | 2.97 | 3.61 | 3.49 |
| Carbon—metallized(gem) | 50 | 20.0 | 207 | 2.50 | 3.03 | 4.14 |
| Tantalum..... | 40 | 22.35 | 221.6 | 1.79 | 2.32 | 5.54 |
| Tungsten (Masda)..... | 40 | 38.8 | 381 | 1.03 | 1.32 | 9.52 |

**27. The color values** of these lamps are shown through spectrophotometric values in Par. **25.*** White light (black body at 5,000 deg. abs.) is taken as standard. As compared with white light, all these incandescent lamps depart so largely that the differences among the several lamps seems relatively small. As a matter of fact, differences, for example, between the color of light from a Masda lamp and that from a carbon lamp are far from negligible.

**28. The flicker of lamps upon alternating current** is important, when operation upon the lower frequencies is considered. Flicker phenomena are so complicated by a number of physical and physiological factors, that no unqualified definite statement can be made as to the lowest frequency upon which lamps may be operated without causing undue annoyance. The variables which enter into the problem are chiefly the following:

Physical

Flicker is less for positive resistance temperature coefficient (as tungsten) than for negative coefficient (as carbon).

Flicker is less for thick filament of given substance than for a thin filament.

Physiological

Flicker is less noticeable when illumination intensity is low.

Eye is most sensitive to flicker when light enters at about 45 deg. from centre of field of view, and falls upon peripheral portions of retina.

Stroboscopic data, showing extreme variation in candle-power through a half cycle, are presented in Fig. 8.† These show the gradual decrease in

Digitized by Google

range of flicker as the frequency is increased; and the more marked flicker when the finer-filament lamps are operated at a given frequency. They indicate that the tungsten lamp is less adaptable for use upon low-frequency currents than the carbon lamp.

Experience indicates that while lighting from 25-cycle circuits is satisfactory for many purposes, yet is not entirely satisfactory for all classes of service with all sizes of lamps. This frequency appears to be just a little too low to be generally acceptable.

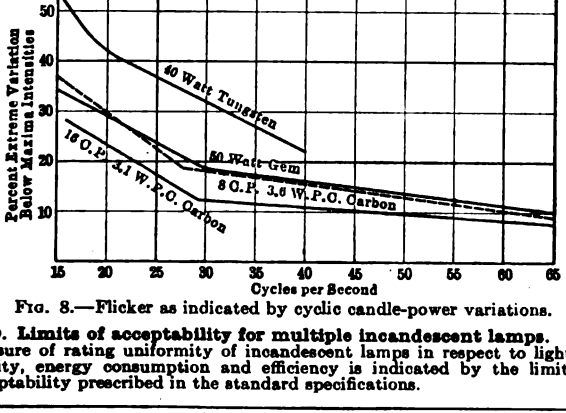

FIG. 8.—Flicker as indicated by cyclic candle-power variations.

**29. Limits of acceptability for multiple incandescent lamps.** The measure of rating uniformity of incandescent lamps in respect to light intensity, energy consumption and efficiency is indicated by the limits of acceptability prescribed in the standard specifications.

| Type | Watts | Permissible variation from standard rated values | | |
|---|---|---|---|---|
| | | c-p. | watts | watts per candle |
| 105 to 125 volts... | ..... | ..... | ..... | ..... |
| Tungsten (Mazda). | 40 | ..... | ± 15 per cent. | ± 8 per cent. |
| Gem..... | 50 | ±7.5 per cent. | ± 7 per cent. | ..... |
| Carbon..... | 50 | ± 15 per cent. | ± 11 per cent. | ..... |

**30. Spherical reduction factor.** It has been customary, when dealing with incandescent lamps, to measure and rate them in terms of mean horizontal candle-power. As for most purposes, the total light produced is the quantity to be considered, it is often desirable to reduce these values to mean spherical candle-power. The ratio of the mean spherical to the mean horizontal candle-power is the spherical reduction factor. For certain lamps this is shown as follows:

| | Approximate spherical reduction factor |
|---|---|
| Treated carbon-oval filament..... | 0.82 |
| Metallized carbon (Gem) oval filament..... | 0.82 |
| Tantalum..... | 0.77 |
| Mazda, 60 watts..... | 0.78 |

**32. The life performance for the various lamp types** is treated in Par. **33** to **83**. In general, however, the life is variable to a marked degree, and it is necessary to consider averages of large groups of lamps rather than the performance of a few samples before drawing conclusions concerning values. Also it is to be borne in mind that the only generally applicable statistics of performance are those obtained in a laboratory under reproducible and ideal conditions of operation. In service the performance may vary largely. All performance data given herein must be qualified to the extent that it may not be strictly applicable to a given set of operating conditions.

## CARBON-FILAMENT LAMPS

**33. Classification.** These may be divided according to filament characteristics into "untreated" (Par. **36**), and "treated" (Par. **34**) carbon-filament lamps.

**34. The treated carbon filament** (having a coating of graphitic carbon deposited by flashing in an atmosphere of hydrocarbon vapor) is the standard carbon filament employed in most lamps manufactured from 1893 to about 1908. The principal sizes and corresponding statistics appear in Par. **35**.

**35. Treated carbon-filament lamps**

| Rated and average watts | Mean horizontal c-p. | Total lumens | Commercial rating watts per mean horizontal c-p. | Specific consumption watts per mean spherical c-p. | Specific output lumens per watt | Average total life |
|---|---|---|---|---|---|---|
| 20 | 4.82 | 50.4 | 4.15 | 5.05 | 2.52 | 1,500 hr. |
| 25 | 8.07 | 83.5 | 3.10 | 3.74 | 3.34 | 500 hr. |
| 30 | 9.29 | 96.0 | 3.23 | 3.91 | 3.20 | 1,050 hr. |
| 50 | 16.83 | 174.5 | 2.97 | 3.61 | 3.49 | 700 hr. |
| 60 | 20.20 | 209.4 | 2.97 | 3.61 | 3.49 | 700 hr. |

**36. Untreated carbon filaments** are now employed principally in sign lamps of the 10- and 20-watt sizes of the 110-volt range, and in lamps of the 220-volt range. As the filament has a higher resistance, it is shorter and may be disposed in a small bulb, where the longer treated filament cannot be utilized. As they are capable of only 30 to 40 per cent. of the useful life of treated-filament lamps, they are operated at a lower efficiency and are used only where necessary. Abroad, notably in England, they have been employed much more generally than in America, due to the prevalence of 220-volt circuits. See Fig. 9.*

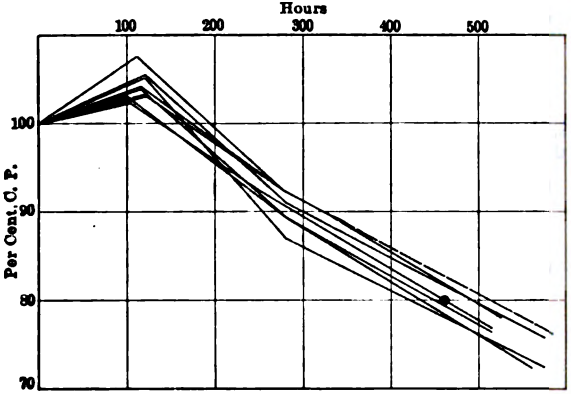

FIG. 9.—Typical candle-power performance of 16 c-p., 220-volt, "untreated" carbon-filament lamps at 3.8 watts per mean horizontal candle-power.

**37. Untreated carbon-filament lamps**

| Rated and average watts | Mean horizontal c-p. | Total lumens | Commercial rating watts per mean horizontal c-p. | Specific consumption watts per mean spherical c-p. | Specific output lumens per watt | Average total life |
|---|---|---|---|---|---|---|
| 105 to 125 volts | | | | | | |
| 10 | 2.0 | 21.2 | 5.0 | 5.88 | 2.12 | 2,000 hr. |
| 20 | 4.8 | 51.2 | 4.15 | 4.88 | 2.56 | 1,000 hr. |
| 200 to 260 volts | | | | | | |
| 35 | 7.95 | 84.0 | 4.40 | 5.24 | 2.40 | 1,000 hr. |
| 60 | 16.26 | 170.4 | 3.69 | 4.40 | 2.84 | 750 hr. |
| 120 | 32.52 | 340.8 | 3.69 | 4.40 | 2.84 | 750 hr. |

**38. Candle-power-performance curves** of typical high-grade treated carbon filament lamps are given in Fig. 10, being a combination of curves published by several lamp manufacturers from independent tests of their products.

**39. The candle-power deterioration** throughout life is due in approximately equal parts to decrease in watts occasioned by increase in filament resistance, and to increase in absorption of light due to bulb blackening.

* Howell. *Transactions* American Institute of Electrical Engineers, June 19, 1905.

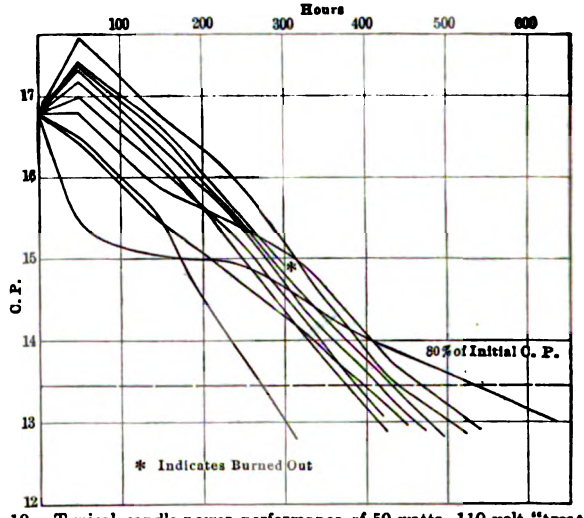

FIG. 10.—Typical candle-power performance of 50-watts, 110-volt "treated" carbon-filament lamps at 2.97 watts per candle.

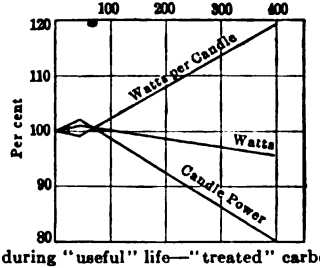

FIG. 11.—Change during "useful" life—"treated" carbon-filament lamp.

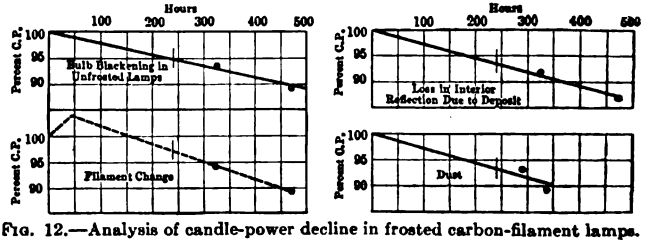

FIG. 12.—Analysis of candle-power decline in frosted carbon-filament lamps.

Digitized by Google

Fig. 11 shows change in candle-power, watts and watts per candle of an average high-grade treated carbon filament lamp throughout useful life.

**40. Frosted carbon-filament lamps decline in candle-power** at about twice the rate of clear lamps. An analysis of the cause of such decline appears in Fig. 12.*

**41. Performance on direct current compared with alternating current.** So far as is known there is no material difference between the performance of carbon lamps on direct-current and on 60-cycle sine-wave current.

**42. The rating uniformity of treated carbon-filament lamps** is suggested in Figs. 13 and 14, which exhibit extremes of good and bad practice.

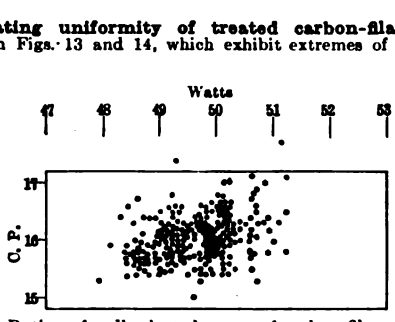

FIG. 13.—Rating of well-selected group of carbon-filament lamps.

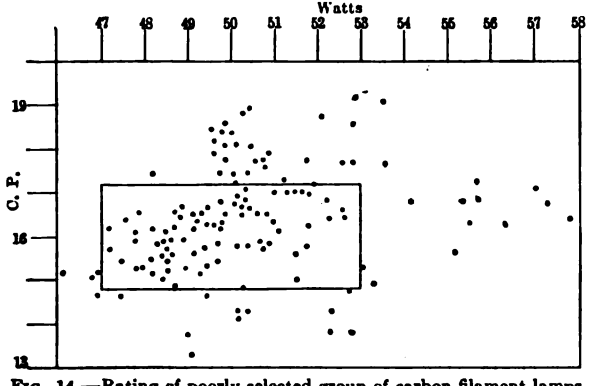

FIG. 14.—Rating of poorly selected group of carbon-filament lamps.

**43. Passing of the treated carbon-filament lamp.** At the present time (summer, 1914) the treated carbon-filament lamp is almost obsolete. The higher efficiency of tungsten (Masda) lamps and of metallised (Gem) carbon lamps, has rendered the use of carbon-filament lamps very uneconomical, and the demand for them has almost ceased.

## METALLIZED CARBON-FILAMENT LAMPS

**44. In manufacture** this filament is baked in an electric furnace before being treated or flashed. After treatment a second baking at high tempera-

* Millar. *Electrical World*, 1907, Vol. XLIX, p. 798.

Digitized by Google

ture in an electric furnace so changes the structure of the outer flashed coating as to give the filament a positive temperature coefficient throughout the ordinary operation range of temperatures. As this feature is characteristic of refractory metals, the filament has been called metallized carbon. It is of lower specific resistance than the treated carbon filament, and consequently, a longer and thinner filament is employed for a given voltage and wattage. The filament is more fragile and more liable to failure through entanglement, drooping and attraction of static charge in the bulb. These disadvantages, however, are more than outweighed by the higher efficiency as compared with treated carbon.

$$\frac{\text{metallized}}{\text{treated}} = 119 \text{ per cent. efficiency.} \qquad (5)$$

**45. Filament shape.** As first manufactured, the metallized carbon-filament was disposed in two hairpin loops. It is now given the standard oval loop. In the earlier years of manufacture, the lamp performance suffered seriously from early burn-outs. The performance of the present-day product in the laboratory compares very favorably with the treated carbon-filament lamp in this respect.

**46. The tendency toward the replacement of the treated carbon-filament lamp by the metallized filament lamp** is indicated by the

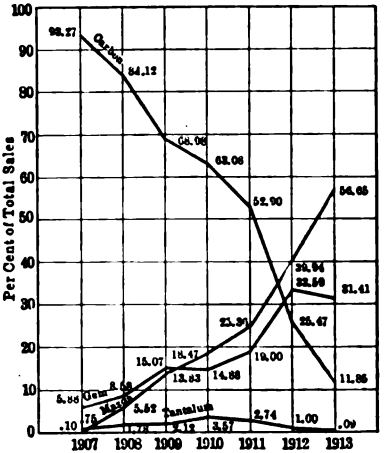

FIG. 15.—Annual demand for incandescent lamps of various types.

diagram, Fig. 15. The large increase in the use of the metallized-filament lamp in 1909 was due to its adoption for free renewal purposes by the large central stations. That of 1912 was occasioned by its strenuous exploitation by lamp manufacturers.

**47. The performance of these lamps** is indicated in Fig. 16 for the 80-watt size.* Each dot shows by its location the hours of failure and the approximate candle-power just prior to failure. One curve shows the average candle-power of all survivors at any number of hours. A second shows the number of survivors. The third shows the change in total light produced by the group of lamps, assuming that failures are not replaced. Typical

average performance data for 50-watt Gem lamps is given in Fig. 17, and the candle-power decline of a group of lamps is illustrated in Fig. 18.

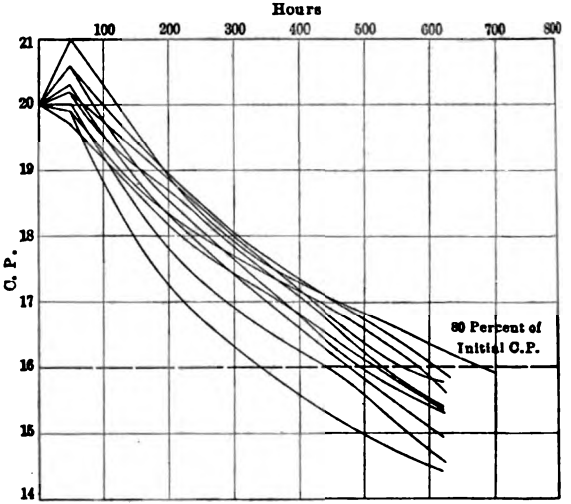

FIG. 18.—Life performance of typical group of 50-watt Gem lamps at 2.5 w.p.c.

### 48. Metallized-filament (Gem) lamps

Principal sizes now produced

| Rated and average watts | Mean horizontal c-p. | Total lumens | Commercial rating watts per mean horizontal c-p. | Specific consumption watts per mean spherical c-p. | Specific output lumens per watt | Average total life |
|---|---|---|---|---|---|---|
| 20 | 5.0 | 52.0 | 4.00 | 4.85 | 2.6 | 1,000 hr. |
| 30 | 10.0 | 103.8 | 3.00 | 3.64 | 3.46 | 1,050 hr. |
| 40 | 15.6 | 162.0 | 2.56 | 3.10 | 4.05 | 600 hr. |
| 50 | 20.0 | 207.5 | 2.50 | 3.03 | 4.15 | 700 hr. |
| 60 | 24.0 | 249.0 | 2.50 | 3.03 | 4.15 | 700 hr. |
| 80 | 32.52 | 336.8 | 2.46 | 2.98 | 4.21 | 700 hr. |
| 100 | 40.65 | 422.0 | 2.46 | 2.98 | 4.22 | 650 hr. |

**49. Performance on direct current compared with alternating current.** As in the case of the treated carbon-filament lamps, it is believed that there is no material difference in performance between direct-current and 60-cycle alternating-current operation.

**50. Rating uniformity** is of the order indicated in Figs. 13 and 14 for treated carbon-filament lamps.

**51. Abdication in favor of the tungsten lamp.** The increase in efficiency made possible in the metallised carbon-filament lamp has been dwarfed by that of the tungsten-filament lamp. The latter already has replaced it in most installations where attention is paid to lighting. The metallised carbon-filament lamp attained premier position among lamp

Digitized by Google

sales in 1912. Already this place has been surrendered to the tungsten-filament lamp. Probably the metallised carbon-filament lamp will become obsolete within the next few years.

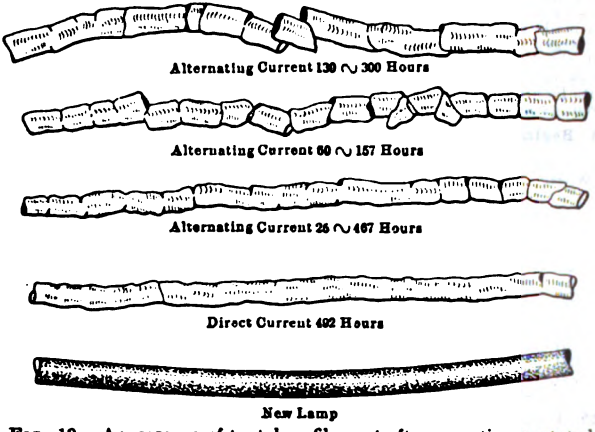
## TANTALUM FILAMENT LAMPS

### 52. Standard tantalum lamps

(Employed in very small quantities)

| Rated and average watts | Mean horizontal c-p. | Total lumens | Commercial rating watts per mean horizontal c-p. | Specific consumption watts per mean spherical c-p. | Specific output lumens per watt | (On d.c.) average total life |
|---|---|---|---|---|---|---|
| 25 | 12.7 | 126.0 | 1.97 | 2.56 | 5.04 | 800 hr. |
| 40 | 22.35 | 221.6 | 1.79 | 2.32 | 5.54 | 600 hr. |
| 50 | 27.93 | 277.0 | 1.79 | 2.32 | 5.54 | 600 hr. |
| 80 | 44.69 | 443.2 | 1.79 | 2.32 | 5.54 | 500 hr. |

**53. Performance upon alternating current.*** The tantalum lamp performs less acceptably upon alternating current than upon direct current. Fig. 19 shows the breaking up of the filament after burning upon an alternating current circuit. From this, the character of the effect which is responsible for the inferiority on alternating current is apparent.



Alternating Current 130 ∿ 300 Hours
Alternating Current 60 ∿ 157 Hours
Alternating Current 25 ∿ 467 Hours
Direct Current 492 Hours
New Lamp

FIG. 19.—Appearance of tantalum filament after operation as stated.

### 54. Comparative performances on various frequencies*

| Nature of supply | Hours "Useful Life" |
|---|---|
| Direct current | 606 |
| 25 cycles | 324 |
| 60 cycles | 151 |
| 130 cycles | 122 |

* *Transactions* American Institute Electrical Engineers, November 23, 1906.

**55. Application limited.** The tantalum lamp, a German development, never attained large use in America. The filaments were imported by American manufacturers who first placed the lamp upon the market in 1906. The tungsten-filament lamp was announced so soon after the tantalum lamp became available, that the latter suffered by comparison. Inferior in efficiency, hardly available for alternating-current work, it yielded to the tungsten lamp without a struggle. In this country its regular manufacture has been abandoned.

## TUNGSTEN-FILAMENT LAMPS (VACUUM TYPE)

**56. Early processes of filament manufacture.** The earliest successful manufacture of tungsten filament lamps was in 1906. There were three pioneer processes of filament manufacture, as follows: (a) that of Just and Hanaman, who deposited tungsten upon a very fine carbon-filament core, afterward removing the carbon and sintering the tungsten; (b) that of Kusel who produced a colloidal solution of tungsten, and after bringing it to a suitable consistency squirted it to the desired diameter, and sintered it; (c) that of Von Welsbach (after the osmium process) who prepared a paste of finely divided tungsten mixed with an organic binder, and squirted it. The thread thus formed was reduced and sintered.

**57. Early American manufacture.** Tungsten-filament lamps were produced commercially in America early in 1907. These were made by the Welsbach process. The lamps made by the General Electric Company corresponded to the Osram lamp as produced by the Auer Company in Berlin. Those made by the Westinghouse Lamp Company followed the processes and construction adopted for the Osmin lamp by the Osmium Lamp Company of Vienna. The earlier styles and sizes in which the tungsten lamp was made available were complementary to carbon-filament lamps. Thus the larger sizes of multiple (100–130 volt) lamps were produced beginning with the 100-watt size for multiple circuits. This most happily introduced the lamp in a manner which led to gradual and constructive replacement of its less efficient predecessors. The development of the smaller sizes followed, as shown in Par. **58**.

**58. Beginning of commercial use of Mazda lamps in the United States**

| Watts | Pressed filament | Drawn wire | "Getter"* introduced |

| 150 | During 1909 | March, 1911 | October, 1911 |
| 250 | During 1909 | March, 1911 | October, 1911 |
| 400 | During 1910 | During 1911 | During 1911 |
| 500 | During 1909 | During 1911 | During 1911 |

**59. Fragility of early types.** These pressed or squirted filaments were quite brittle when cold. They were mounted as short hairpin loops, held rigidly at or near the loop. In the smaller sizes particularly it was necessary to observe great precaution in order to avoid filament breakage in shipment, and even after installation.

**60. Fragility reduced.** The quality of the lamps was improved rapidly, and, to some extent, the early fragility was overcome. The ruggedness of a tungsten lamp depends chiefly upon the strength of the filament, and upon the manner in which the filament is mounted. The first notable event in the direction of ruggedness was the development of a long pressed filament wound continuously upon an arbor in a manner not dissimilar to that previously adopted in the tantalum lamp. The filament ends, however,

* See Par. **66**.

Digitized by Google

were attached to the lead wires in a special manner which contributed to the ruggedness of the lamp.*

**61. Drawn wire.** This was followed shortly by the announcement that tungsten wire had been drawn, and that drawn-wire tungsten lamps had been made successfully. Wire thus drawn was perfectly ductile, but, in the process of exhausting the bulbs and burning for a short time in the factory, much of the ductility was destroyed. Nevertheless, by employing a long filament of this wire, wound continuously as in the tantalum lamp, a much stronger tungsten lamp was achieved than previously had been available. Some idea of the increase in strength of the filament itself is given by the diagram in Fig. 20.†

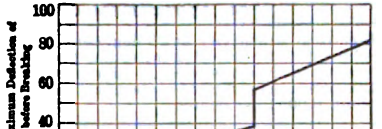

FIG. 20.—Increasing strength of tungsten filaments.

**62. Modern manufacture of tungsten lamps.** "The raw material used in the filament factory is a concentrated ore of tungsten, from which pure tungstic oxide, a fine-grained yellow powder, is obtained. This is 'doped' and reduced to tungsten metal by hydrogen in an electric furnace; the metal produced being in powder form, rather coarse grained, gray in color, and very heavy. This tungsten powder is formed into ingots about $\frac{1}{2}$ in. square and 6 in. long, by pressure alone, no binder being used. The pressure, which is very great, is applied transversely and compacts the tungsten so that the ingot can be handled. It is then placed in an electric furnace in an atmosphere of hydrogen and heated to a white heat, the effect of this heat being to compact and strengthen the ingot and make it a good conductor of electricity. The ingot is then placed in an atmosphere of hydrogen and heated to near the melting point, long enough to thoroughly sinter the ingot. The ingot now has a high luster, and the powder particles of which it is composed are welded together quite firmly. The square ingot now goes to a swaging machine. It is heated to white heat, taken out into the open air and swaged. During this operation a cloud of tungstic oxide rises from the ingot. The ingot is reheated and swaged several times before the square ingot becomes round. The heating and swaging are continued until the ingot is changed to a rod, $\frac{3}{100}$ in. in diameter and 30 ft. long. Before this, when the rod is about $\frac{9}{100}$ in. in diameter, it begins to have a fibrous structure. At $\frac{3}{100}$ it has a well-developed fibrous structure, but can easily be broken by bending back and forth once or twice.

From thirty mils the rod or wire is reduced in size by hot drawing through diamond dies. The wire is heated to a bright red heat and is still red hot after passing through the die. This degree of heating is continued until the wire is only three mils in diameter, which is about the size of the filament in a 100-volt, 100-watt lamp. Below this, the temperature of drawing is reduced and the last drafts of any wire are made below red heat. The wire is now quite ductile and the last drafts may be made cold if desired. During this drawing the wire is lubricated with graphite, which forms a coating and prevents oxidation of the wire. It also lubricates the wire when it passes through the die. The last draft is made through a very perfect die which reduces the diameter of the wire very slightly, and in this way very long pieces are made which are the same size throughout."‡

Wire so produced is cut accurately to length and is wound upon the filament supports. A bulb-blackening preventive is introduced. After

Digitized by Google

being sealed into the bulb, the lamp is placed upon the pumps and while being heated to a high temperature the bulb is evacuated. During the exhaustion process, the passage of current through the filament is reduced to a minimum. The candle-power of a lamp so produced is slightly lower than its rated or initial value. A brief "**aging**" brings it to or nearly to its true initial value.

**63. Photometry.** The process of manufacture has now been standardized so thoroughly that lamps of standard sizes are made accurately and are not photometered, though samples of each run are usually photometered as a check upon the manufacturing.

**64. Approximate data on tungsten***

Electrical Resistivity at 25 deg. cent.
Hard drawn wire—6.2 microhms per cm. cube.
Annealed drawn wire—5.0 microhms per cm. cube.
Temperature coefficient of electrical resistivity between 0 deg. and 170 deg. cent. 0.0051 per degree.

| Diameter (in.) | Tensile strength (lb. per sq. in.) | Specific gravity |
|---|---|---|
| 0.150 | ..... | 19.30 |
| 0.005 | 490,000 | ..... |
| 0.0029 | 530,000 | ..... |
| 0.0015 | 600,000 | 20.19 |

**65. Current inrush.** Tungsten has a positive temperature coefficient, and the resistance is relatively low when the filament is cold. This results in a marked inrush of current when the lamp is lighted. For illustrative data, see Fig. 21.†

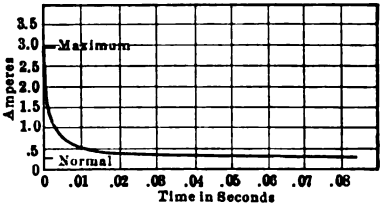

FIG. 21.—Current inrush at starting—multiple tungsten lamp.

**66. "Getters."** (See Par. **58.**) Recently the candle-power maintenance of the lamp has been improved by the introduction of a **bulb-blackening preventive** which, to a marked extent, reduces loss of light due to bulb blackening. These include substances which appear to react chemically with the tungsten which is evaporated from the filament, forming a nearly transparent deposit on the bulb instead of the dense tungsten deposit; and also substances which unite with the evaporated tungsten, forming a product which is decomposed by the incandescent filament, depositing the tungsten again upon the filament. Prior to the application of these materials the candle-power maintenance of the smaller lamps was excellent, but that of the larger lamps, 150 watts and above, left much to be desired. The bulb-blackening preventive has therefore been most efficacious in these larger types.

**67. The growth of the use of tungsten lamps** is shown in Fig. 15, sales of carbon and Gem lamps being shown for a comparison.

**70. Efficiency rating of Mazda (tungsten) lamps**
(November, 1914)

| Rated and average watts | Mean horisontal c-p. | Total lumens | Commercial rating watts per mean horizontal c-p. | Specific consumption watts per mean spherical c-p. | Specific output lumens per watt |
|---|---|---|---|---|---|
| 10 | 7.7 | 75 | 1.30 | 1.67 | 7.52 |
| 15 | 13.0 | 128 | 1.15 | 1.48 | 8.52 |
| 20 | 18.2 | 178 | 1.10 | 1.41 | 8.91 |
| 25 | 23.8 | 234 | 1.05 | 1.34 | 9.34 |
| 40 | 38.8 | 381 | 1.03 | 1.32 | 9.52 |
| 60 | 60.0 | 588 | 1.00 | 1.28 | 9.80 |
| 100 | 105.0 | 1,032 | 0.95 | 1.22 | 10.32 |
| 150 | 167.0 | 1,635 | 0.90 | 1.15 | 10.90 |
| 250 | 278.0 | 2,725 | 0.90 | 1.15 | 10.90 |
| 400 | 444.0 | 4,524 | 0.90 | 1.11 | 11.31 |
| 500 | 556.0 | 5,655 | 0.90 | 1.11 | 11.31 |

**71. Conduction losses.** The tungsten filament, being long, must be supported at a number of points throughout its length. At each point the filament is cooled by heat conduction. The loss of efficiency resulting from such cooling is material. Tests by Hyde, Cady and Worthing* have shown efficiency loss of about 7 per cent. in pressed filament tungsten lamps of 25 and 60 watts.

**72. The average life of 110-volt-type Mazda lamps** is guaranteed to be 1,000 hr. The actual life in the laboratory usually is considerably longer. Improvements in the lamps have been rapid, and it is the avowed purpose of the manufacturer to increase the efficiency from time to time as improvements in the lamps warrant. Yet so conservatively has this principle been applied that with few exceptions a life of satisfactory duration has been realized. It is not practicable to state life values which may be relied upon for any considerable length of time because of likelihood that these will be altered due to efficiency changes. No better guide to the useful life of the American lamps can be offered than the life guarantee of the manufacturers which is given in Par. **73**.

**73. Life guarantee of Mazda lamps†**

| Rated watts | Average useful life |
|---|---|
| 10 | 2,000 hours |
| 15 | 1,000 hours |
| 20 | 1,000 hours |
| 25 | 1,000 hours |
| 40 | 1,000 hours |
| 60 | 1,000 hours |
| 100 | 1,000 hours |
| 150 | 1,000 hours |
| 250 | 1,000 hours |
| 400 | 1,000 hours |
| 500 | 1,000 hours |

**74. The life evaluation‡** of lamps is a subject upon which thought is being expended. The term "useful life" meaning hours to 80 per cent. of initial candle-power or earlier failure is applied arbitrarily.

* *Transactions*, I. E. S., Vol. VI, 1911, p. 258.

† These values refer to the average life of a group of suitable size, operated with good regulation at rated efficiency. The performance of the individual lamps in any group is apt to be inconsistent, and it is therefore important to consider a sufficient number of samples to assure a fair average value.

**75. Loss of light due to frosting of bulbs***

| | Per cent. loss of light* | |
|---|---|---|
| | Bowl frosted | All frosted |
| Straight side bulbs, 25 to 250 watts..... | 3 | 8 |
| Round bulbs, 25 to 40 watts..... | 5 | 8 |

**76. Influence of external temperature upon the performance of lamps.** But little information is available on this subject. Among carbon-filament lamps it has been found that relatively high external temperatures (200 deg. fahr.) result in a few poor-vacuum lamps, which "slump" in candle-power. This presumably is due to the water vapor expelled from the glass at the higher temperature. Among Masda lamps more care is taken to eliminate water vapor, and this effect, not very serious among carbon lamps, should be less noticeable in the performance of Masda lamps.

**77. Influence of the character of the current supply** upon the performance of Masda lamps is not available as conclusive data. It has been asserted that differences in wave form of alternating current affect the performance materially. This is not accepted, however, and the weight of evidence appears to indicate the contrary. It is known, furthermore, that the performance on respectively sine-wave 60-cycle current and direct current does not differ enough to influence practice.

**78. Concentrated filaments.** An improvement effected in 1913 is the winding of the filament in a very fine helix which greatly reduces its length and makes possible modified forms of lamps. This concentrated filament† is employed in lamps designed for projection work in which it is important to reduce the over-all dimensions of the light source. It also has been used in tubular lamps for show-cases. The life of such lamps is shorter than that of lamps of the standard type.

**79. Linolite lamps** are a special form of tubular lamps particularly adapted for use in lighting show-cases, and other spaces for which their dimensions are favorably adapted. No data are available as to the relative life of such tubular lamps and ordinary bulb lamps at a given efficiency.

## TUNGSTEN FILAMENT LAMPS FILLED WITH INERT GAS

**80. General effects of the gas.**‡ As a result of work of the Research Laboratory of the General Electric Company it has been found that inert gas within the bulb of a tungsten lamp operates to: (a) cool the filament; (b) reduce the rate of evaporation; (c) convey the evaporated material to the top of the bulb. The problem of increasing the efficiency of tungsten lamps—at least those having stouter filaments—is that of avoiding bulb blackening, which is the life-limiting feature.

The cooling effect of an inert gas decreases the candle-power of the filament, and in this respect the gas is detrimental. To obtain the same efficiency as in a vacuum it is necessary to increase the watts and operate the filament at a higher temperature. On the other hand the gas pressure reduces the

rate of evaporation, and the convection currents set up within the bulb deposit in the upper part of the bulb such tungsten as may be evaporated. The cooling effect is greater, of course, in the case of the smaller-diameter filaments. In fact, among the smaller sizes of lamps for multiple circuits the cooling effect is so great that these do not benefit by this improvement. Among filaments which operate at greater current values, the disadvantage of the cooling effect is more than compensated by the advantages listed above. The stouter the filament the greater the benefit derived, and the higher the efficiency at which it can be operated without decreasing the life.

**81. Sizes and types.** This remarkable improvement in Mazda lamps appears to be applicable therefore to the following classes of lamps: low-voltage lamps 2-amp. (or more), 110-volt 100-watt (and larger); street series lamps of 3.5 amp. (and greater), and of all candle-powers. It results, therefore, in creating a new high-power illuminant of efficiency which becomes higher as the size of the lamp is increased. It is a formidable competitor of the arc-lamp in a field in which the arc-lamp has held exclusive sway. It even leads the way into a range of higher-power illuminants than have been available among arc-lamps. It results in marked efficiency increase in existing sizes of incandescent lamps in the street-series type and in the larger multiple lamps—100 watts and above.

**82. The construction** of these lamps differs considerably from that of the existing types of Mazda lamps. To take full advantage of the action of the

## GENERAL CHARACTERISTICS OF ARC LAMPS

**84. The electric arc** is unstable on constant-voltage supply because of its volt-ampere characteristics whereby the voltage decreases as the current is increased. It is essentially a constant-current device. When used upon multiple circuits, ballast resistance, if direct-current, or reactance, if alternating-current, must be placed in series with the arc to limit the current. All arc lamps must be provided with automatic operating mechanisms to start the arc and to feed the electrodes as they are consumed. In addition, lamps for series service must be provided with shunt devices which protect the lamp and maintain the circuit in case the lamp fails to operate.

**85. Operating mechanisms** usually are actuated by electromagnets or solenoids, often in conjunction with weights and dashpots or other restraining device. "Series lamps," having series magnets only, regulate for constant current in the lamp. "Shunt lamps," employing shunt magnets only, regulate for constant voltage. The more usual "differential lamp" is equipped with both series and shunt magnets, and regulates for constant relation between current and voltage. Much ingenuity has been displayed in developing feeding mechanisms for arc lamps. Numerous methods have been employed, among which may be mentioned the gravity, clutch, rocker-arm, brakewheel, clockwork, motor and hot-wire feeding devices. These applications are described in publications of manufacturers and the principal methods are described in text-books.

**86. Classification of arc lamps.** Arc lamps may be classified in a number of ways according to the viewpoint. The classifications adopted in Par. **87** are comprehensive. In the following pages the several types of arc lamps are discussed in the order indicated. Vacuum tube lamps, which might be included in this class, are discussed later (Par. **116**).

**87. Descriptive classification of types**

| Conventional description | Nature of electrodes | Types of lamp | Chief light production from | Methods of light production |
|---|---|---|---|---|
| Carbon-arc. | Pure carbon. | Open, Enclosed, Intensified. | Incandescent electrodes. | Principally incandescence of electrode ends—some little light from arc by luminescence. |
| Flame-arc. | Mineralized carbon. | Short burning. Long burning. | Luminous arc. | Selective radiation from vapors or gases which are in arc stream as result of vaporization from electrodes, especially from the anode. Some little light from incandescent electrode ends. |
| Magnetite and luminous arcs. | Metallic. | Regular Ornamental (inverted). | Luminous arc. | Luminescence of arc into which light-giving elements are brought from cathode by electro-conduction. |

NOTE.—All lamps are available in alternating-current types as well as in direct-current types except those of the third group, equivalent of which is expected to be produced in the "titanium" arc-lamp, exclusively for alternating-current service.

## CARBON-ELECTRODE ARC LAMPS

**88. The open arc** is now regarded as obsolete. In its most common form it was of the direct-current 9.6-amp. type—the old "full arc" to which the rating of "2,000 c-p.," was applied in earlier years. The arc is about $\frac{1}{16}$ in. (0.48 cm.) long and of low luminosity. The end of the negative (lower) electrode, after a few hours of burning, assumes a conical shape and yields some little light by incandescence. The end of the positive (upper) electrode becomes concave, and the "crater" thus formed is the chief source of light produced by the lamp, the process being that of incandescence. Only the feeble light from the arc itself is produced by luminescence. The end of the positive electrode becomes intensely hot, attaining at the hottest part of the crater to from 3,900 to 4,000 deg. cent.*

**89. Light distribution from the open arc.** Fig. 24 shows the open carbon arc.† It will be apparent at once that the lower electrode obstructs a large portion of the light emanating from the crater. The curve in Fig. 25 shows actual distribution of light compared

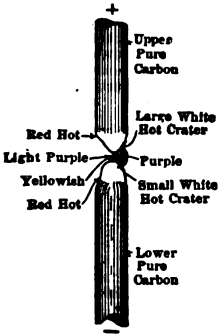

FIG. 24.—Open carbon arc.

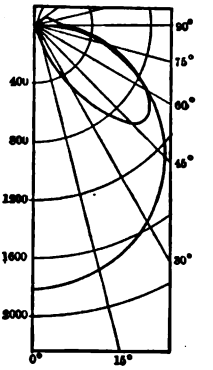

FIG. 25.—Distribution of light in vertical plane about 9.6-amp. direct-current open arc lamp. Also estimate of distribution if obstruction of lower electrode could be avoided.

with probable distribution if the lower electrode were transparent,‡ the difference illustrating the loss of light due to obstruction by the lower electrode.

**90. Photometric and electrical data on direct-current open carbon arc lamps**

| | "Full arc" | "Half arc" |
|---|---|---|
| Amperes | 9.6 | 6.6 |
| Watts | 450 | 325 |
| Mean spherical candle-power | 410 | 240 |
| Maximum candle-power | 900 to 1,200 | ..... |
| Specific consumption—watts per candle | 1.09 | 1.35 |
| Nominal candle-power rating | 2,000 | 1,200 |

**91. Electrode life—open arc lamp.** The open arc lamp suffered from short life of electrodes, unsteadiness of light, and poor light distribution. The electrode life was 7 or 8 hr. and it became common practice to

* Weidner & Burgess. Bulletin Bureau of Standards, Vol. I, No. 1, 19.

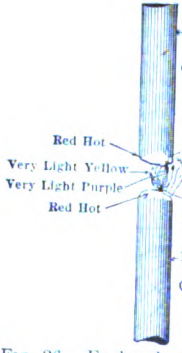

FIG. 26.—Enclosed carbon alternating-current arc.

employ two pairs of carbons, the second pair to replace automatically the first pair after these had been consumed, thereby securing continuous operation long enough for one night. These disadvantages were sufficient to occasion the general abandonment of the open arc lamp in favor of the enclosed carbon arc lamp which became available commercially in 1894.*

**92. The enclosed carbon arc lamp** differs from the open arc in that the supply of air at the arc is restricted, thus retarding the rate of consumption of carbon, and securing an electrode life of 100–125 hr.; the arc is about $\frac{1}{2}$ in. (0.95 cm.) long, requires from 70 to 80 volts, and adds appreciably to the violet light produced; the ends of the electrodes are nearly flat. The anode does not have a marked crater, and does not become so hot as in the open arc. Less light is produced per watt. A representation of the arc of an alternating-current enclosed lamp is given in Fig. 26.† The enclosed arc lamp has been manufactured in a wide variety of forms. Some of these with approximate data are listed in Par. **93.**

**93. Data on enclosed carbon arc lamps**

| | Auxiliary | Watts | Mean spherical candle-power | Watts per mean spherical candle-power | Power-factor (per cent.) |
|---|---|---|---|---|---|
| Series alternating current, 6.6-amp. | Opal inner and reflector | 430 | 130 | 3.30 | 84 |
| Series alternating current, 7.5-amp. | Opal inner and reflector | 480 | 155 | 3.09 | 85 |
| Series direct current, 6.6 amp. | Opal inner and reflector | 490 | 260 | 1.88 | ... |
| Multiple direct current, 115 volts | Clear inner—opal outer | 550 | 165 | 3.33 | .... |
| Multiple direct current, 115 volts | Clear inner—opal outer | 715 | 240 | 2.98 | .... |
| Multiple alternating current, 115 volts | Clear inner—opal outer | 430 | 145 | 2.97 | 70 |
| Multiple alternating current, 115 volts | Clear inner—opal outer | 540 | 190 | 2.84 | 70 |

**94. Status of enclosed arc lamp.** The enclosed arc lamp proved superior to the open arc lamp in (a) steadiness; (b) characteristic of light distribution; and (c) electrode life. More effort was expended in developing it and equipping it with suitable glassware and, in the case of alternating-current lamps, with reflectors. In spite of its inefficiency, it prevailed over the open arc lamps, and remained the standard lamp for street lighting until the advent of the metallic-electrode lamp.

**95. Efficiency and light distribution—enclosed carbon arc lamps.** The efficiency of the arc is lower in the alternating-current type. Both elec-

Digitized by Google

trodes are raised to a high temperature, but neither attains the high temperature of the anode in the direct-current arc. The characteristics of light distribution from the two types of lamps appear in Fig. 27. It is general practice to equip the alternating-current lamps with a reflector which directs, below the horizontal, some of the light which would otherwise be distributed above the horizontal. The multiple lamps are less efficient than the series lamps. A certain amount of ballast is necessary, and this accounts for the difference between the line voltage (100 to 120 volts), and the arc voltage (70 to 75 volts). If the circuit is for alternating current, a reactance is employed, which does not occasion a large wattage loss but reduces the power-factor. If a direct-current circuit, a resistance is used, which occasions a direct loss in watts.

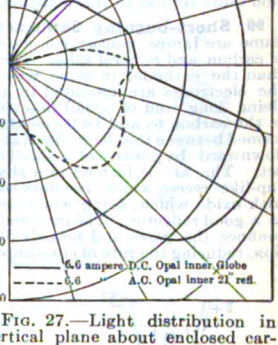

FIG. 27.—Light distribution in vertical plane about enclosed carbon arc lamps.

**96. Intensified carbon arc lamps.** The efficiency of a carbon arc lamp may be increased by diminishing the diameter of the electrodes with a given current or by increasing the current with given electrodes. In intensified carbon arc lamps the diameter of the carbons is reduced, producing a gain in efficiency and a light which is more nearly white and steadier than that of the ordinary enclosed arc lamp of which it is a refinement. Such lamps are used chiefly for lighting interiors where white light is desired, as in clothing stores. The intensified carbon arc was developed in Europe and exploited in small sizes operating at 2 and 3 amp., with an electrode life of 20 hr. or less. In this country the developments were along the lines of somewhat larger lamps operating at higher currents and longer electrode life. Typical lamps of this type are somewhat smaller than ordinary enclosed arc lamps, and are designed for either direct-current or alternating-current service. Small-diameter electrodes (about 7 mm.) are used, and life of about 70 hr. is realized. With opal globes an efficiency corresponding with approximately 2 watts per mean spherical candle-power is obtained in the direct-current lamp. The General Electric Company has developed a lamp of this type for direct-current service, in which two converging 6-mm. upper-positive carbons are used with a vertical lower carbon of 9.5 mm. diameter. This lamp is somewhat larger and more substantially built than other lamps of the class. The specific consumption when employed with an opal globe is slightly more than 2 watts per mean spherical candle-power.

## THE FLAME ARC LAMP

**97. Nature of flame arc.** Impurities in the carbon are detrimental in the arc lamp of types in which the chief light production is accomplished through the incandescence of the electrode ends. As carbon is the most refractory material known, impurities are always more volatile, and their presence tends to reduce the temperature of the electrode ends. Hence, in the manufacture of carbons for such lamps, purity is considered of first importance. In the flame arc, the purpose is to secure light from the arc rather than from the electrode ends. The carbon is impregnated with chemicals which, when volatilized and driven into the arc, become highly luminous. The lower temperature of the carbon ends, due to these impurities, is immaterial, since little dependence is placed upon the ends for light production. The flame arc is simply a carbon arc into which mineralized salts are introduced. These may be of calcium, for yellow light; of barium and titanium, for white light; and of strontium, for reddish light. The carbon electrode serves as an electrical conductor and assures a hot and steady arc. The chemicals with which it is impregnated include those which are efficient light producers, and others whose functions are to promote high arc temperature and to steady the arc.

Digitized by Google

**98. Theory of light production.** The electrode ends, especially the anode, are brought to a high temperature, vaporising the carbon and the metallic salts. The succeeding processes of light production are largely a matter of speculation at the present time. Some opinion favors luminescence as the process by which light is produced, other attributes it to favorable selective radiation from incandescent particles in the arc stream. An approved theory assumes the chemicals to become dissociated by the heat of the inner core of the arc (which is known to be hotter than the outer sheath) and to recombine in the outer sheath with evolution of heat, which tends to maintain the temperature of the arc. According to this view, the light is produced by luminous particles in process of combustion, which is a condition quite similar to that existing in ordinary flame.

**99. Short-burning flame arc lamp.** The electrodes for short-burning flame arc lamps, consist commonly of carbon tubes packed with a mixture of carbon and mineral salts. The anode is usually more highly mineralised than the cathode, in some cases the cathode is pure carbon. As a rule the electrodes are mounted in an inclined position illustrated in Fig. 28. Being long and of small diameter a copper wire is sometimes imbedded in the carbon to add to its conductivity and mechanical strength. The arc formed between the electrodes is arched downward by means of a small magnet. The arc is formed in a shallow cup-like recess which becomes coated with oxide which, being white, serves as a good reflector. The inverted cup confines the gases and retards oxidation, reducing the rate of consumption,

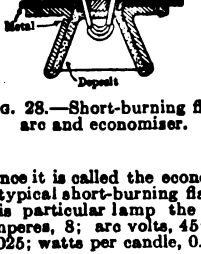

FIG. 28.—Short-burning flame arc and economiser.

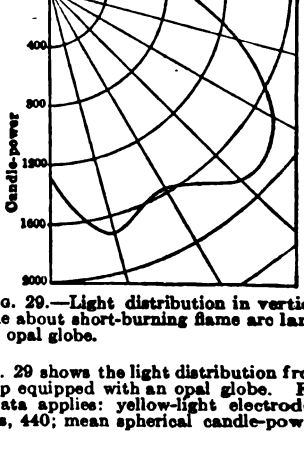

FIG. 29.—Light distribution in vertical plane about short-burning flame arc lamp with opal globe.

hence it is called the economiser. Fig. 29 shows the light distribution from a typical short-burning flame arc lamp equipped with an opal globe. For this particular lamp the following data applies: yellow-light electrodes; amperes, 8; arc volts, 45; total watts, 440; mean spherical candle-power, 1,025; watts per candle, 0.43.

**100. Status of short-burning flame arc lamp.** In this country the short-burning flame arc lamp has come into use chiefly for display lighting. Its maintenance cost has proven too high for most utilitarian purposes.

**101. Flame arc lamps of medium electrode life.** The obvious inadequacy of electrode life of the earlier forms of flame arc lamps led to attempts to increase that life. Magazine lamps have been devised having two to ten sets of carbons, and attaining electrode life of 30 to 40 hr. These, however, have not come into use in this country. The Jandus lamp devised in England and later placed upon the market in this country attains 70 hr. It is called a "regenerative" lamp, because the gases containing light-giving chemicals are conveyed from above the arc through external tubes to the bottom of the globe, again to be entrained in the arc. The electrodes are vertically coaxial and special in construction. The specific consumption of the lamp is about 0.6 watt per mean spherical candle-power.

## LONG-BURNING FLAME ARC LAMPS

**102. General features.** With the development of flame arc lamps which have an electrode life of 100 hr. or more, the flame arc has been placed in a position to compete with other illuminants for street-lighting service. In this type, electrodes of about ½ in. (2.22 cm.) diameter are employed within a globe which restricts the air supply. It is known as the "long-burning" or "enclosed" flame arc. Long electrode life is secured at the expense of some efficiency. For this type of lamp, solid impregnated carbons have been developed in place of the familiar cored carbons employed in the original flame arc lamps. These are available in both yellow and white light forms, the latter being slightly less efficient. See Fig. 30.*

**103. Electrical characteristics of flame arc lamps** of one manufacture appear in Par. 104. To adapt the alternating-current lamps for use upon various circuits, compensators are supplied, sometimes built in and sometimes external to the lamp proper.

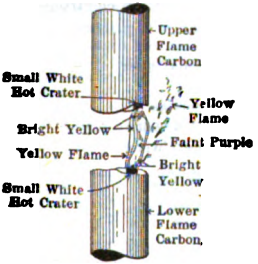

FIG. 30.—Long-burning flame arc.

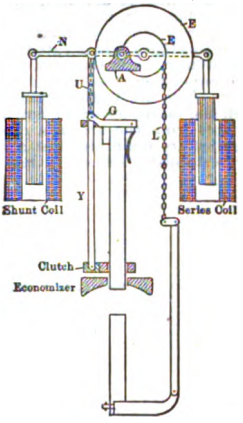

FIG. 31.—Mechanism of long-burning alternating-current flame arc lamp.

**104. Approximate electrical data of long-burning flame arc lamps of one manufacture**

| | Amperes | | Volts | | Terminal watts | Power-factor, per cent |
|---|---|---|---|---|---|---|
| | Terminal | Arc | Terminal | Arc | | |
| Alternating-current multiple 110-volt (compensator) | 7.5 | 10.5 | 110 | 47 | 540 | 66 |
| Alternating-current series..... | 10.0 | 10.0 | 60 | 47 | 465 | 78 |
| Alternating-current series (compensator) | 7.5 | 10.0 | 86 | 47 | 500 | 78 |
| Alternating-current series (compensator) | 6.6 | 10.0 | 98 | 47 | 500 | 78 |
| Direct-current multiple 110-volt. | 6.5 | 6.5 | 110 | 67 | 715 | ..... |

**105. Life of electrodes.** Carbons for enclosed flame arc lamps are usually of ½ in. diameter and are 14 in. long. The unused portion of the upper is used for trimming the lower. A life somewhat in excess of 100 hr. is had. The mechanism of an alternating-current enclosed flame arc lamp of one make is illustrated in Fig. 31.

* Blake and Couchey. "Arcs and Electrodes," *Gen. Elec. Review*, 1913, p. 497.

Digitized by Google

**106. Efficiency values may be stated** only in a general way. The efficiencies of carbons of different makes vary. Also the efficiency of a given make of carbons varies when used in lamps of different makes. Approximate values for these lamps are indicated in Par. **107**, but the data should be applied in a qualified way.

**107. Efficiencies of 10-amp. long-burning flame arc lamps with "white" electrodes** are as follows: Mean spherical candle-power, 700; watts, 520; watts per mean spherical candle-power, 0.74.

## THE METALLIC-ELECTRODE ARC LAMP

**108. Nature of arc and electrodes.** This lamp differs radically from other arc lamps in that light is produced by luminescence of vapor brought into the arc stream by electro-conduction from the cathode. The arc of one form of this lamp is illustrated in Fig. 32.* The cathode consists of magnetic oxide of iron with titanium as the chief light-giving element, and other ingredients to serve as steadiers and vaporisation retarders. The anode is of copper. The arc is fixed, and a small reflector is located advantageously within the lamp, directing downward and outward much of the light which emanates from the arc in a direction above the horizontal. The metallic electrodes are maintained at a relatively low temperature, and the arc will not re-establish itself every half cycle as with hot carbon electrodes. This

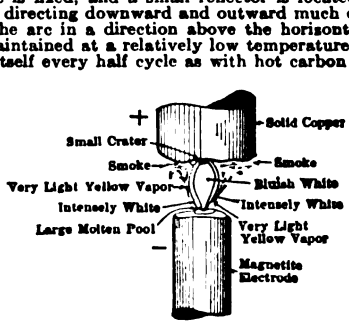

FIG. 32.—Magnetite arc.

limits the lamp to operation upon direct current or rectified current. With lower current values the lamp is more effective than the carbon arc lamp, 4 amp. being standard, with a current value of 6.6 amp. growing in popularity. A most recent development provides a 5-amp. system, and higher-efficiency electrodes for operation at all three current values.

**109. Metallic-electrode lamps for series circuits**

| Type | Amperes | Volts | | Watts |
|---|---|---|---|---|
| | | Terminal | Arc | Terminal |
| Magnetite—Standard | 4.0 | 78 | 76 | 312 |
| | 6.6 | 78 | 76 | 515 |
| Magnetite—Ornamental | 4.0 | ..... | ..... | ..... |
| | 6.6 | 78 | 76 | 515 |
| Metallic Flame—Standard | 4.0 | 73 | 71 | 290 |
| | 6.6 | 68 | 66 | 450 |

**110. Candle-power and efficiency.** Par. **111** shows photometric data on metallic-electrode lamps as produced early in 1914. The manufacturers call attention to the fact that the natural distribution of light from the arc is not unlike that from a Mazda lamp, but that, in adapting the lamp for commercial street-lighting service, a reflector is placed over the arc, and the light distribution is modified as shown in two of the curves of Fig. 33 at the expense of from 20 to 25 per-cent. loss of light.

* Blake and Couchey. *Gen. Elec. Review*, 1913, p. 497.

**111. Photometric data on magnetite arc lamps, standard electrode**

| | Volts | Watts | Mean spherical candle-power | Watts per mean spherical candle-power |
|---|---|---|---|---|
| 4-amp.—clear globe | 78 | 312 | 240 | 1.30 |
| 6.6-amp—opal globe, internal reflector | 78 | 515 | 695 | 0.74 |
| 6.6-amp.—ornamental-alabaster globe | 78 | 515 | 725 | 0.71 |

NOTE.—The new (Autumn, 1914) electrodes result in a gain of about 45 per cent. in efficiency, over that shown above for standard electrodes. A 5-amp. lamp has been added to the schedule, giving, with the new electrode, about the same light as the present 6.6-amp. lamp.

**112. Light distribution characteristics.** The distribution of light about three types of magnetite arc lamps is shown in Fig. 33, manufacturers' data being employed.

**113. Regulating mechanism.** In Fig. 34 are shown the essential regulating features of the magnetite lamp.* The electrodes are separated when no voltage is applied at the lamp terminals. When the circuit is energized, the electromagnet *O* raises its core *D*, bringing the lower or negative electrode *A* into contact with *B*, starting the arc. This closes the circuit through series coil *S* and short-circuits *OR*, releasing *D* and allowing the lower electrode *A* to drop into its position as fixed by the clutch *Q*. As *A* is consumed, the shunt magnet *P* is strengthened, withdrawing core *F* until finally the shunt circuit *OR* is closed at *MN* and the arc is restruck. This mechanism regulates for constant arc length.

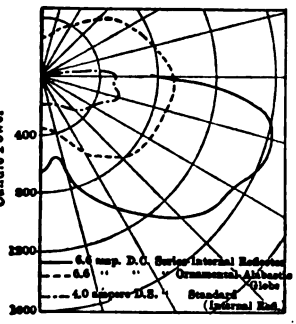

FIG. 33.—Distribution of light in vertical plane about magnetite arc lamps.

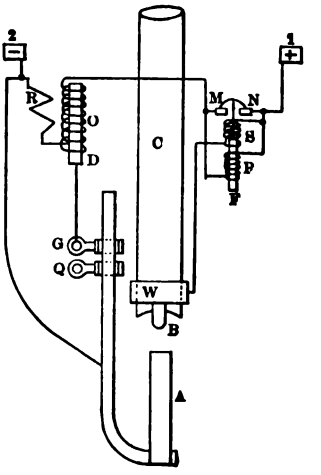

FIG. 34.—Regulating mechanism of magnetite arc lamp.

**114. The ornamental magnetite lamp** is a modification of the standard form, the regulating mechanism being placed below the arc. In efficiency and operating characteristics it is quite similar to the standard pendant lamp.

* Steinmetz. "Radiation, Light and Illumination," p. 158.

Digitized by Google

**115. The titanium-carbide lamp** was brought to an interesting stage of development in 1909, but did not enter into commercial practice.* As compared with the magnetite lamp it was of higher efficiency and was available in smaller units. It was withdrawn for further development without having reached the commercial stage. At this writing it is understood that the lamp has been improved and is still under development. No published description of the new form is available. It is understood, however, that with an electrode life of 100 hr. or more, the lamp efficiency corresponds with about 0.65 watts per candle, its distribution characteristic being similar to that of the magnetite lamp. The light is yellower than that of the magnetite lamp.

## TUBE LAMPS

**116 Vacuum arcs.** The volt-ampere characteristics of a vacuum arc differ from those of an arc in air. Within certain limits the voltage is substantially constant throughout a range of current variation.

**117. Low-pressure mercury arc.** In the mercury-vapor lamp, mercury which is the cathode, is vaporised as soon as the arc is struck. In the column of vapor formed within the tube and attaining a pressure of 1 to 2 mm. light is produced by luminescence, the arc being relatively cool, of the order of 200 to 250 deg. cent. for the low-pressure glass-tube lamp. The anode located at the other end of the tube is of iron or graphite, and the tube at this end is enlarged to form a condensing chamber from which the condensed mercury finds its way back to the cathode.

**118. Starting the mercury arc.** In starting the lamp, the tube may be tilted until a thin stream of mercury connects the two electrodes. When the tube resumes normal position breaking of this stream starts the arc. The tilting may be done manually or automatically by means of an electromagnet. An alternative methcd of starting the arc consists in effecting a momentary high-voltage discharge by means of an induction coil. Other means have been tried with some success.

**119. Alternating-current mercury arc.** The mercury arc is a unidirectional conductor and is essentially suited for direct-current operation. For operation upon alternating current, it is necessary to maintain the correct polarity and to adopt some expedient which will prevent the current at the cathode from decreasing to such a low value each half cycle that the arc cannot be restarted. One way of accomplishing this is to connect the cathode through a resistance and an inductance to the middle of a transformer winding placed across the supply mains. Two anodes are provided in the tube, one connected to each side of the supply, while a third, for starting purposes, is connected through a resistance to one side. With this arrangement (Fig. 35) the cathode is negative with respect to one or the other anode throughout the entire cycle. The inductance maintains the current well above zero. A ballast is sometimes used to steady the arc under conditions of fluctuating potential.

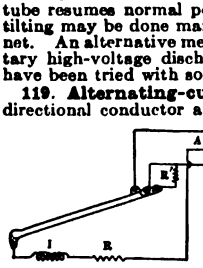

FIG. 35.—Electrical connections of alternating-current mercury arc lamp.

**120. Data on low-pressure mercury-vapor lamps**

| Supply | Length of light-giving tube, in. | Terminal volts | Amperes | Watts | Power-factor | Approximate mean spherical candle-power (initial) | Watts per candle |

**121. Data on low-pressure mercury arc lamps.** Data upon commer- l forms of Cooper Hewitt low-pressure lamps are given in Par. 120. The es employed are about 1 in. in diameter and are in length about 1 for one and one-third volts of the vapor column. A life of about 4,000 is claimed for the tubes, with a candle-power decline of about 25 per t. in the first 1,000 hr.

**122. Color.** The light given by the low-pressure mercury vapor lamp is enish-blue, and is without red rays (Fig. 4, Par. 8). This bars the lamp m use for many purposes. It has been found to be well adapted for use, wever, in installations where color values are of little importance, as in nt shops, warehouses, some factories, drafting rooms, etc. It has been nd to have peculiar value in work where fine detail discrimination is uired.

**123. Correcting the color.** Attempts have been made to correct the or value of the mercury vapor lamp. Other materials, tungsten for exam- , have been employed with mercury. The mercury lamps have been used combination with incandescent lamps.* Ives† reports that one candle- wer mercury vapor light, mixed with 0.54-candle-power tungsten-lamp t, yields a good white light for general purposes. Hewitt has employed a orescent paint to transform some of the radiation in the green portion of spectrum into radiation of longer wave length.

**124. High-pressure mercury arc lamp.** In order to benefit by the her efficiency obtainable at high vapor pressure an evacuated tube of

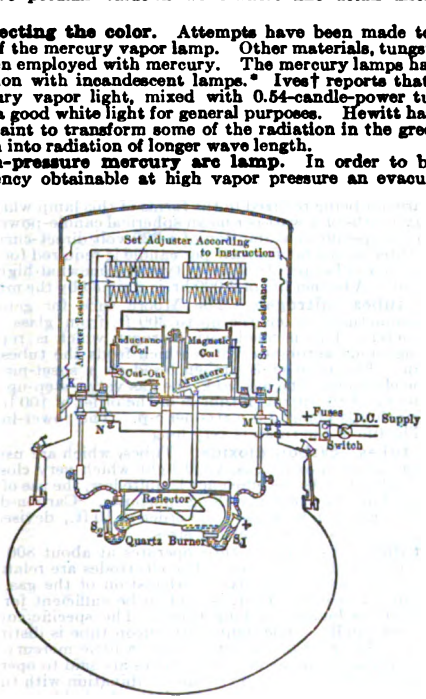

FIG. 36.—High-pressure, quarts-burner mercury arc lamp.

ed quarts is used, as glass softens at a lower temperature than that uired. The lamp is operated upon the same basic principles as underlie operation of the low-pressure lamp. The cathode is of mercury and the ode is of mercury or tungsten. The quarts tubes (burners) are 5 to 10 long. The operating mechanism, illustrated in Fig. 36, is equivalent that of the low-pressure lamp.

Digitized by Google

In starting, the tube is tilted by an electromagnet, which is short-circuited as soon as the arc is struck by the breaking of the conducting stream of mercury. At first the current is high, about three times normal, and the arc voltage is very low, the excess voltage being taken up by the ballast resistance. The lamp gives relatively little light and that of an abnormally green color. The heavy current quickly vaporizes the mercury, increasing the vapor pressure and resistance of the arc. Gradually a condition of normal operation is approached, and, after about 15 min. current and voltage at the arc are of substantially correct values. It is understood that lamps are being developed, or have been developed, for alternating-current service and for series service.

**125. Data on high-pressure mercury vapor lamps**

| Direct-current supply | Burner volts | Current | Terminal watts |
|---|---|---|---|
| 110 | 85 | 3.8 | 418 |
| 220 | 165 | 3.3 | 725 |
| 550 | 345 | 2.0 | 1,100 |

**126. Efficiency and life of quartz lamps.** But little is published regarding the efficiency of the quartz lamp. Difficulty in photometry of its greenish light may account for this, at least in part. Experience in this country shows, however, that early reports of very high efficiency, which emanated from Europe, are not being realized in the forms of this lamp which have been developed. Six-tenths of a watt per mean spherical candle-power seems indicated as the initial specific consumption of a 220-volt direct-current multiple lamp. About three quarters of a watt per candle is required for the 110-volt multiple direct-current lamp. In a series type a somewhat higher efficiency should be realized. A burner life of 2,000 hr. is claimed by the manufacturers.

**127. Moore tubes—nitrogen.** The Moore tube for general lighting purposes is manufactured in lengths up to 200 ft. from glass tubes about 1.75 in. in diameter. This is filled with nitrogen which is replaced as required by an ingenious automatic valve which feeds the tubes at intervals of about 1 min. The tube ends are enclosed in a sheet-metal box containing the tube electrodes, the gas tank, the gas valve, step-up transformer, etc. The efficiency of the nitrogen tube is of the order of 100 lumens per ft. and the consumption is about 2.5 watts per c-p. The power-factor is about 75 per cent. The life of the tubes is very long.

**128. Moore tubes—carbon dioxide.** Tubes, which are usually shorter when employing carbon-dioxide gas, yield light which very closely approximates average daylight. As the efficiency is quite low, the use of these tubes is practically confined to color-matching purposes. Carbon-dioxide tubes have been manufactured in lengths of the order of 10 ft., devised to form a daylight window, and also in the smaller sizes.

**129. Neon tubes.** A six-meter tube operates at about 800 volts. The tubes are of about 1.75 in diameter. The electrodes are relatively large in order to reduce vaporization and avoid exhaustion of the gas. The tubes have a limited life, which, however, is said to be sufficient for commercial purposes. The life is longer for long tubes. The specific consumption is about 0.6 watt per candle. The light of the neon tube is distinctly lacking in blue radiations. In order to correct for this, a little mercury is employed in some of the tubes, with the neon. Such tubes are said to operate at about 1.0 watt per candle. When used in certain combination with tubes containing pure neon, a light which closely simulates daylight in appearance is obtained. A modified form of neon tube in which tubes of much smaller diameter are employed, is arranged to form script letters which serve for electric signs.

## ACCESSORIES FOR ILLUMINANTS

### GENERAL PRINCIPLES

**130. The purposes commonly served by lighting accessories are as** follows: (a) redirection of light; (b) concealment (partial or complete) of light source; (c) decoration. Local conditions peculiar to the installation determine choice and the weight to be given of these factors.

**132. Reflectors.** Since light sources commonly are located in the upper parts of rooms, and since the light is utilised chiefly in the lower part of the room, the most common form of auxiliary consists of an inverted bowl or a cone-shaped cover for the lamp, provided with an inner reflecting surface designed to redirect more or less of the light downward. Such reflectors are available in great variety; Par. 131 indicates the more common types classified with respect to various characteristics.

**133. Redirection of light.** A large proportion of the light emitted by a source may be intercepted and much of it may be redirected in the desired direction. The extent to which redirection is effected depends upon the following factors: (a) proportion of total flux intercepted by reflecting surface; (b) shape of reflecting surface; (c), properties of reflecting surface.

**134. Light intercepted.** Assume that opaque reflectors are made of various shapes and with a reflecting surface which absorbs 25 per cent. of incident light, whatever its direction. A reflector which is substantially flat intercepts, say, 40 per cent. of the total light flux. Another which covers the lamp fairly well intercepts say 80 per cent. of the flux. The flat reflector therefore occasions a loss of 10 per cent. of the total light flux, while the other results in a loss of 20 per cent. but is much more effective in redirecting a goodly proportion of the flux.

**135. Reflector design.** An ever-present obstacle in the design of reflectors for general illumination purposes is the relatively large area of the light source (lamp filament) as compared with the surface area of the reflector. If the light source were, in effect, a point, the reflector-design problem would be simplified. Dealing with a source of considerable area, the reflecting surface must be so designed as to redirect, in the desired direction, the light which it reflects, while allowing a minimum of flux to fall a second time upon a part of the reflector. Improper shape of reflecting surface, however favorable the reflection coefficient of the surface, may impair efficiency to a large extent by directing some of the flux back into the reflector instead of out and in the desired direction.

**136. Reflecting surfaces.** A glossy or polished surface may reflect specularly or regularly, rendering an imperfect image of the source. Such surfaces are mirrors, polished aluminum, enamel and some glasses. Or the surface, if mat or depolished, may reflect the light irregularly or diffusely, as aluminumised steel, etched glass, etc. As a rule surfaces of the former class are the more efficient reflectors. Among surfaces employed for reflectors differences in absorption range from 25 to 75 per cent. Usually, the more efficient surfaces permit of more accurate control of light redirection.

**137. Concealment of light sources.** This has long been regarded as an essential of good illumination when bright light sources are employed. Exposed light sources occasion glare and decrease visual power. One of the serious difficulties encountered among the earlier designs of reflectors was the exposure of the light sources. During recent years this tendency has been overcome to a great extent, and the great majority of reflectors now produced conceal the source at least from ordinary view. Devices whose primary function is the concealment of the light source are often referred to as **shades.** This term is likewise applied to many lighting auxiliaries in which the decorative feature is dominant to the exclusion of efficiency in redirection of light. For most purposes a reflector may be of value in concealing the light source as well as in redirecting the light.

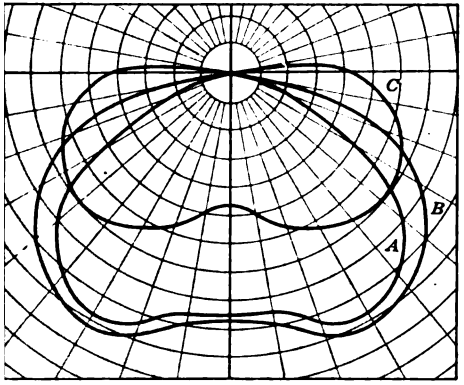
**138. Distribution characteristics.** In Fig. 37 are indicated the shapes and relative sizes of three reflectors, and the character of the distribution of light when used with a Mazda lamp.*

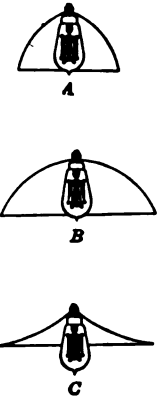
"Reflector *A* resembles a parabola in shape with the lamp so placed as to obtain the greatest degree of concentration, and its angle of cut-off is considerably smaller than for *B*; consequently, one might expect this unit to produce by far the higher candle-power in a limited zone near the tip. It is seen, however, that from the standpoint of efficiency, even throughout a narrow zone, nothing can be gained by the use of an enamel reflector of small diameter. The maximum intensities produced by units *A* and *B* are practically identical, but the efficiency of *B* in the 50-deg. or wider zones is considerably higher than the corresponding value for *A*.

* Bulletin 20, National Electric Lamp Association.

Digitized by Google

"The distribution shown in curve *A* may be classed as intensive. By placing the lamp somewhat lower in the reflector, a more extensive distribution of light may be secured which will be preferable for most locations requiring a general illumination. This form of curve, so far as distribution in the lower hemisphere is concerned, is practically ideal for industrial lighting purposes where the lamps are suspended at usual heights. The form of this curve is desirable both because it tends toward a uniform illumination on the work, and because the lamp filaments are well screened. On the other hand, it must be remembered that the wider reflector, *B*, will in practically all cases supply 10 or 15 per cent. more useful light than can be obtained from a bowl-shaped unit in either the intensive or extensive position. Furthermore, the shadows resulting from the use of a light source of large diameter, such as *B*, are less sharp than those from *A*."





| Percentage Light Flux | | | |
|---|---|---|---|
| Unit | *A* | *B* | *C* |
| Total Light from Lamp | 100.0 | 100.0 | 100.0 |

FIG. 37.—Light redirection by reflectors of various shapes.

**139. Data on reflectors.** In Par. **140** are given statistics of reflectors used with 100-watt Mazda lamps, showing the light absorbed by the reflectors, some characteristics of the distribution obtained, and some physical data on the reflectors.

## REFLECTORS FOR INDUSTRIAL LIGHTING

**141. Porcelain-enameled reflectors.*** "Any practical reflecting surface absorbs a considerable percentage of the light incident upon it. When incandescent lamps were first used in industrial lighting, the efficiency of porcelain as a reflecting surface was recognized, and various translucent reflectors of this material came into extensive use. However, they were not found entirely successful because they were lacking in mechanical strength; in many locations breakage resulted, causing the loss of the reflector and, which was more serious, often damaging material or injuring employees. It was largely for this reason that they were replaced by the

familiar tin cone reflectors which, though less efficient, had the advantage of greater mechanical strength. The difficulties that were met in the first attempts to enamel a metal surface with porcelain which has a high reflecting power and adheres without cracking, have been overcome, and to-day the porcelain-enameled steel units are most frequently employed in industrial plants. They combine with the strength of a metal shell the high reflecting power of porcelain. Such a surface absorbs approximately 35 per cent. of the incident light."

**142. Light absorption.** The most effective porcelain-enameled reflectors intercept the light which is more than 60 deg. above the nadir and redirect it with a loss of about 30 per cent. of the total flux. The absorption, however, varies considerably with the quality of the enameling.

**143. Enamel-paint reflectors.** "Metal reflectors with a surface of white enamel paint are available at prices materially lower than those asked for the porcelain-enameled products. However, owing to the relatively rapid depreciation of this surface and to the fact that these reflectors are seldom designed with proper regard for the efficient distribution of light, their use is likely to result in the waste of a considerable portion of the money annually expended for lighting. A loss of even 10 to 20 per cent. of the light in this manner will each year amount to several times the added cost for the most efficient equipment.

**144. Aluminumised reflectors.** "Aluminumised reflectors have approximately the same initial efficiency as the porcelain enameled, and allow a better control of the direction of light rays. Moreover, their cost is lower than that of porcelain-enameled equipment. On the other hand, reflectors of this class have heretofore failed to maintain their high initial efficiency in service. Their use is, therefore, to be recommended only where a better control of the light flux—for example, a concentrated distribution—is desired. An aluminumised surface has recently been developed which is superior to the older forms in maintaining efficiency.

**145. "Mirrored-glass reflectors** form another class of opaque units which find some application in industrial lighting. These reflectors make possible a control of light rays even better than that secured with the aluminumised units. They excell in efficiency the other classes of equipment discussed, and the best mirrored reflectors appear to retain their efficiency with practically no loss throughout life. Their cost, however, is higher than for the other units, and, in common with all glass reflectors, they are limited to those locations where breakage is not a serious matter. They are especially valuable where a concentrated light is required."*

**146. Prismatic-glass reflectors.** Like other relatively fragile reflectors these may be used only where danger of breakage is small. They are not subject to the action of fumes or gases as some metal reflectors. They are extremely efficient, and where high concentration of light is desired, they are superior to white-glass reflectors.

**147. Opaque reflectors.** Certain further comments of an impartial nature are excerpted from a paper by Powell,† and an article by Stickney and Powell.‡ "The great majority of industrial reflectors are of the opaque diffusely reflecting types. The reflecting surfaces may be of enameled porcelain, white-enamel paint, or aluminum either painted or mat. The enameled porcelain reflectors are especially advantageous, if of a high quality, because of ease of cleaning, resistance to acid fume, resistance to heat, and ability to withstand weather in outdoor service. These reflectors are perhaps not quite so efficient when new as those finished in white paint and as usually designed do not yield so wide a range of distribution characteristics as do some other types of reflectors.

"Aluminum-finished reflectors offer a wide range of distribution characteristics, and are efficient and satisfactory when new. In most forms they are liable to serious depreciation due to the collection of dust, and as a result of cleaning. One manufacturer now markets an aluminum-finished reflector

which has a coat of lacquer, which is said to facilitate cleaning and render the surface permanently efficient.

"Mirror reflectors are of high efficiency and offer opportunities for a wide range of design, as to light distribution. Compared with other industrial reflectors, they are however somewhat costly and fragile."

## REFLECTORS FOR COMMERCIAL LIGHTING

**148. Translucent reflectors.** In commercial lighting opaque reflectors are rarely used except in show windows. It is a usual requirement that considerable light shall be thrown upon the ceiling and walls which dictates the employment of translucent reflectors. As commercial lighting offers, perhaps, the readiest field for the sale of new types of lighting auxiliaries, a wide variety of translucent-glass reflectors has been designed. This type includes prismatic glass and a great variety of white glass, as opal, phosphate glass, etc. In each type these reflectors are to be found in various sizes and shapes, differing in light-distribution characteristic. The several types and makes of reflectors differ among themselves in efficiency, light transmission, etc. Where high concentration of light is required, the prismatic-glass reflectors offer some advantage. Among many of the white-glass reflectors there is little choice, except in appearance. The differences are those largely of appearance of the glass itself, and of ornamentation. Neglecting these two features, the white-glass reflectors of various makes are to be grouped naturally in regard to the amount of light transmitted, it being the general order that those which transmit the most light reflect less light downward. As in the industrial reflectors, commercial reflectors may be procured with either glossy or mat reflecting surfaces, the latter being preferable for almost all purposes from the illuminating standpoint, though they require somewhat more cleaning than do glossy-surface reflectors.

**149. Decorative qualities.** Many of the translucent reflectors are of such good design and are so ornamented that they are very pleasing in appearance, and entitled to a place in the class of decorative glassware. Still, others, more appropriately classed as shades, are designed predominantly for decorative effect; these are of very little value where the illumination is to be utilized otherwise than for purposes of decoration. Among the latter are shades of "art" glass and metal or pottery, and of various fabrics. It would be futile to attempt to show data on such shades. On all reflectors intended for industrial and commercial lighting including many which are very decorative in appearance, definite engineering data are available. Typical information of this kind appears in Par. 150.

**150. Distribution of light in various zones about Mazda lamps and inverted bowl reflectors***

| Type of reflector | Typical zonal distribution | | | |

**151. Depreciation due to dust.** Certain information has been published showing the depreciation in reflecting efficiency due to collection of dust on lamps and reflectors in industrial service. Perhaps the most comprehensive data applicable to modern equipments of reflectors and Mazda lamps is that shown in Bulletin 20 of the National Lamp Works of the General

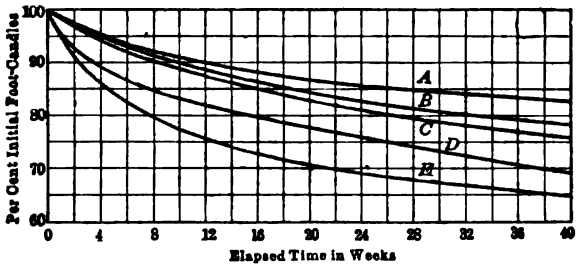

FIG. 38.—Reduction in light due to dust.

*B*. Bowl enameled steel.
*C*. Dense opal glass.
*D*. Prismatic glass.
*E*. Light density opal glass.

Electric Company published October, 1913. This is summarized in Fig. 38. The curves show decrease in illumination on the working plane.

**152. Enclosing glassware.** The sphere commends itself for many purposes of ornamentation and is therefore a popular form in design of lighting auxiliaries. It, with various modifications as to shape, forms an important class. Obviously, light absorptions run higher and light control is less definite than is the case with open-mouth reflectors. In the matter of redirection of light, much may be accomplished in an ordinary glass sphere by varying the location of the light source within the sphere, but the tendency with such glassware is always to yield distribution characteristics which approach a circle. There are some forms of enclosing glassware, however, in which special attention has been given to this phase of the subject with very notable success in the redirection of light. Par. **153** gives some data upon enclosing glassware of various types.

**153. Photometric data upon enclosing glassware employed with 1,000 lumen Mazda lamp***

## BOWLS FOR INDIRECT LIGHTING

**154. Cove lighting.** Recognition some years ago of the need for concealing brilliant light sources from view led to systems of indirect lighting which the light was thrown upon some reflecting surface which became a secondary source of illumination. One method consisted in locating the lamps within a cornice or cove concealed from view and illuminating the room via the ceiling. By this system, control of the light was largely lost, and efficiency of utilisation was very low. In one case reported, only 15 per cent. of the total light produced by the lamps was delivered upon a working plane.* While this low efficiency was perhaps an extreme and better values have been realised, yet the cove lighting system was so inherently low in efficiency as to be unsuccessful.

**155. Indirect lighting fixtures.** A more recent development of indirect lighting is one in which the lamp is located within bowls, usually hung centrally in a room or bay. By backing the lamps with efficient reflectors, and controlling the direction of light, a higher order of efficiency may be obtained and a more desirable direction of the light secured. Indirect lighting systems possess the advantage of high diffusion, and are therefore valued where freedom from shadow and glare is a consideration of primary importance. Some statistics showing the proportion of the total light produced which may be delivered upon a working plane by this system of lighting are given in Par. **156.**

**157. Luminous-bowl.** A recent development is the luminous-bowl indirect-lighting unit. In this fixture the bowl is rendered luminous for purposes of decoration only, it usually being of the same order of brightness as the ceiling immediately above it, which is the principle secondary light source. In some-fixtures in which as much as possible of the light is directed upon the ceiling, small auxiliary lamps are employed for the purpose of rendering the bowl luminous. These may be wired separately, providing, themselves, a feeble illumination which, as an alternative to the use of principal lamps, may be useful for special purposes in certain installations.

## SEMI-INDIRECT LIGHTING UNITS

**158. Translucent bowls.** A development of the past few years consists in the use of glass bowls enclosing the light source and reflecting most of the light to the ceiling, as in the indirect lighting system, while transmitting in various proportions enough light to give an appreciable direct component. Some data upon bowls of this type, of one manufacture, are presented in Par. **160.** Referring to the data in this table it will be seen that the authors have made a study of the influence of contour of bowl upon the distribution of light, and likewise of the influence of optical density of glassware. Their conclusions from these figures and others given in the paper, follow in Par. **159.** Data on semi-indirect installations appear in Par. **163.**

**159. Effect of change of light source and bowl contour.** "The distribution of light is materially affected by changes in the position of the lamps within the bowl; changing from a single lamp to a closely clustered group of two or three lamps does not introduce large variations in the distribution characteristics, although the single lamp results in a somewhat wider distribution above the horizontal. The ratio of light above the horizontal to that below the horizontal in the four types of glass of the contour 3, chosen for this purpose, vary from 1.26 for the least dense (etched glass) to 6.4 for the most dense (Calla); and the effect of change in the contour of the bowls is that with the shallower bowls the distribution both above and below the horizontal is not so wide, more light being centred near the bowls while with the deeper bowls there is, of course, a larger ratio horisontal."

FIG. 39.—Contours referred to in Par. 160.

**161. Reflectors in railway coaches.** Some information upon the distribution of light in a typical railway day coach has been made available by the Committee on Illumination of the Association of Railway Electrical Engineers.‡ While railway-car illumination is to some extent a special problem, yet the behavior of most reflectors in such service is an important indication of what may be expected in other lines. In the tests which are here recorded, the car was equipped with Mazda lamps located in the centre deck or monitor, and spaced at intervals of two and three seats respectively. Conditions in all respects were favorable to lighting efficiency because the equipment was new and clean and operated under correct conditions. As indirect and semi-indirect equipments were used, it is important to note that the coefficient of diffuse reflection of the car ceiling was 65 per cent.

**162. Data on railway-coach lighting.** Results are summarized in Par. **164** which shows a description of the auxiliaries, the total light produced by the lamps, the average intensity of illumination throughout a horizontal plane 33 in. above the floor, the per cent. of the total light produced which is delivered to such horizontal plane and the angle above the nadir at which the lamp filament is screened from view by the reflector. The total horizontal area lighted was 566 sq. ft.

In these railway-car tests open-mouth reflectors are shown to deliver upon the horizontal plane of reference, proportions of the total light which range from a maximum of 59 down to a minimum of 25 per cent. Indirect-lighting equipments with ceiling of the quality stated, deliver upon the plane of reference about 25 per cent. of the total light produced in the car. Slightly better values are shown for the enclosing and the semi-indirect equipments.

## ACCESSORIES FOR SPECIAL PURPOSES

**165. Show-window lighting.** For show-window lighting and certain other purposes an asymmetrical distribution of light is usually required. Example of reflector designed for such a purpose is shown in Fig. 40.

**166. Street lighting.** Various auxiliaries for redirecting part of the light produced by street illuminants have been developed. Some of the most effective in this respect are to be found among the newer designs of auxiliaries for Mazda type *C* (gas-filled) series lamps. Illustration of this is given in Fig. 41. In some street illuminants, as the magnetite and metallic-flame arc lamps, a reflector is built in the lamp casing. In others, the diffusing globes with which the lamps are equipped are so shaped as to modify the distribution characteristic materially. These are inconspicuous methods of accomplishing a measure of light redirection which usually is less marked than that accomplished by the use of external reflectors.

**167. Glass plates.** Translucent glass plates consisting either of frosted glass, opal glass, so-called art glass, ribbed glass or prismatic glass are largely employed as skylights and as diffusing screens for artificial lighting. Some data upon the transmission coefficient of such glasses are given in Par. 169.

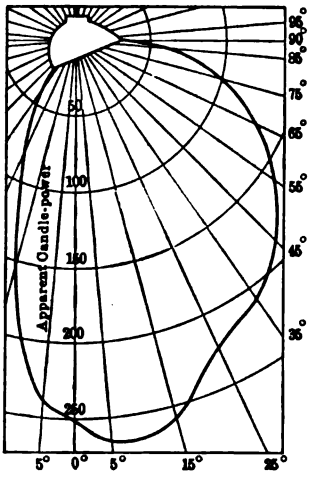

FIG. 40.—Asymmetrical distribution, adapted to show-window lighting.

**168. Glass for redirecting daylight.** Ribbed and prismatic glass is used to a large extent in industrial lighting for directing into large rooms a

Illuminating Engineering Society Lecture Course on Illuminating Engine ing* as follows:

"We may increase the effective light in a room 30 ft. (9.14 m.) deep more, to from three to fifteen times by using factory-ribbed glass instead plane glass in the upper sash of the window. By using prisms, instead plane glass, we may, under certain conditions, increase the effective lig fifty times. The gain in effective light on substituting ribbed glass or pris for plane glass, is much greater when the sky angle is small, as in the ca of windows opening upon light shafts or narrow alleys. The increase in t strength of the light directly opposite a window in which ribbed glass prisms have been substituted for plane glass is at time such as to light a de or table 50 ft. (15.24 m.) from the window better than one 20 ft. (6.1 m from the window had previously been lighted."

**170. Headlights** may be considered in this connection but only in a eral way because the design of headlights is a specialty in itself and has little application in general illuminating practice. An excellent sympo- n on the subject is to be found in recent articles by Messrs. Sugg, Denning- and Porter.* Much attention has been given to the subject of locomo- e headlights and an excellent résumé of state laws on this subject together h comments is to be found in the report of the Committee of Locomotive adlights of the Association of Railway Electrical Engineers.†

## ILLUMINATION CALCULATIONS

### GENERAL CONSIDERATIONS

**171. Light flux.** According to approved concept, light is regarded as inous flux.‡ The output of a lamp is its **total luminous flux.** The ghtness of a diffusely reflecting or transmitting surface is proportional ts **specific luminous flux.** The intensity of illumination received on surface is the **flux density.** Thus inous flux is analogous to magnetic l electrostatic flux. Comprehen- n of light flux is facilitated by con- ering a point source to be located at centre of an imaginary non-reflect- sphere. The total luminous flux duced by a source of 1 c-p. radi- d uniformly, is divided by the num- of unit solid angles or steradians in sphere in order to arrive at the t of luminous flux which is the lu- n "equal to the flux emitted in a t solid angle (steradian) by a point rce of 1 c-p."

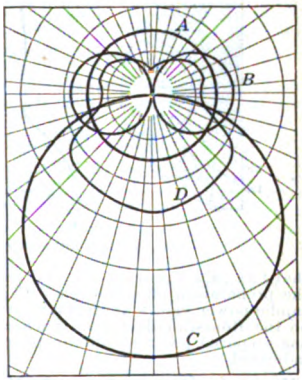

FIG. 42.—Four distributions of a given flux.

**172. Distribution of light.** In ctice, light is rarely radiated uni- mly, and it is therefore necessary to sider the flux to be distributed in a at variety of ways. The deter- nation of light distribution charac- istics of sources, is a regular part of minating engineering practice, and st calculations performed involve s distribution characteristic. In . 42 are illustrated four different tributions of a given luminous flux. e curves show a section of revolution. The circle (curve $A$) indicates uni- m distribution from a punctiform source; curve $B$ shows distribution from a oretical line source, distributing no light at the poles. Curve $C$ shows the tribution from a uniformly radiating circular disc, and curve $D$ shows a ht-distribution characteristic typical of a certain class of reflectors.

### COMPUTATION OF TOTAL FLUX, OR MEAN SPHERICAL CANDLE-POWER

**173. Zonal areas.** In Fig. 43, curve $D$ from Fig. 42 is reproduced. The lar diagram at the left shows the flux density or intensity in any direction, the vertical plane, considered. Referring to the representation of a sphere the right, it will be noted that the total area of a zone of a given altitude at e equator is much greater than the total area of a similar zone near the le. The flux density, or intensity, of the light distributed throughout ch zone, is indicated in the distribution curve to the left. The area of ch zone must be multiplied by the mean flux density, in order to obtain e total flux distributed throughout the zone.

**174. Rousseau's method.** Rousseau's method of determining the tota flux distributed through the zone, is the basis of most such computations This method is indicated in the middle of the diagram. The zone latitudes as represented upon the sphere, are projected upon a rectilinear diagram, upo which the zone widths then become proportional to the areas of the zone upo the sphere. The curve of light distribution, when plotted upon this diagra in the manner indicated, will comprehend an area proportional to the tota luminous flux. The mean altitude of such a curve is proportional to the mea flux density (which is to say, the mean spherical candle-power). Furthe more, the area comprehended in any zone by the curve, is proportional to th zonal flux, and the mean altitude of the curve within that zone is proportiona to the mean flux density or candle-power within that zone. The area com prehended by the curve may be obtained by the use of a planimeter, o by averaging altitudes at short equal intervals. It is apparent, therefor

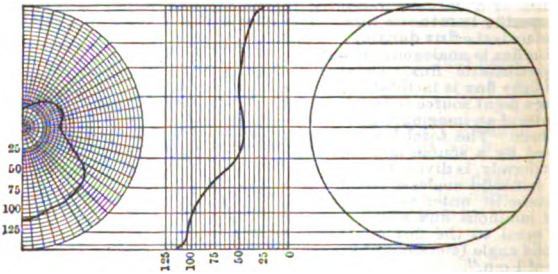

FIG. 43.—Relation between flux and intensity.

that flux values may be obtained from the light distribution curve witho the preparation of a Rousseau diagram, by averaging the flux density c candle-power values at angular intervals corresponding to equal interva on the Rousseau diagram. Such angles are given in Par. 175. Macbet has prepared polar coordinate paper on which such angular intervals a indicated.

**175. Angles from vertical axis at which values may be taken from t light distribution curve and averaged to obtain mean flux density or mean candle-power in each hemisphere**

| Ten points | Six points |
|---|---|
| 18 deg. 63 deg. | 24 deg. |
| 32 deg. 70 deg. | 41 deg. |
| 41 deg. 75 deg. | 54 deg. |
| 49 deg. 81 deg. | 65 deg. |
| 57 deg. 87 deg. | 75 deg. |
| | 85 deg. |

**176. Mean zonal-candle-power constants.** When photometric values of light distribution are available but have not been plotted to form a light distribution diagram, the flux computation may be carried out by the appli cation of the constants in Par. 177, which are proportional to the areas of the several zones of which the test angles are representative. In using these constants, find the product of each candle-power value and the constant for its angle. Divide the sum of all such products by two to determine mean spherical candle-power. Multiply the mean spherical candle-power by 12.57 to obtain total lumens. To determine mean hemispherical candle-power employ same constants except for the 90-deg. value where the given con stant should be divided by two. In this case, do not divide the sum of the products by two.

**178. Kennelly's method.** Kennelly has devised a graphical method of rectilinear construction for determinations similar to those carried on by means of a Rousseau diagram.*

**179. White-Wohlauer method.** The "Fluxolite" diagram facilitates the same kind of computations, but yields total lumens instead of mean candle-power.†

## COMPUTATION OF ZONAL FLUX

**180. Zonal flux.** This does not differ from calculation of total flux. In fact most determinations of total flux or of flux in one hemisphere are merely additions of zonal-flux values. The Rousseau, Kennelly and White Wohlauer methods yield zonal flux readily. Constants for use in determining mean zonal candle-power directly from angular candle-power values are given in Par. 181 for certain zones. Multiply the sum by $2\pi$ (6.28) times the difference between cosines of limiting angles to obtain corresponding lumens.

**181. Constants for use with candle-power values to yield approximate mean zonal candle-power**

**182. Zonal constants approximate only.** In using zonal constants it must be remembered that the candle-power is assumed to represent the mean intensity throughout the zone. In many cases this assumption is not strictly justifiable. Hence this is only an approximation method.

**183. Typical zonal values.** Fig. 44 is a reproduction of a typical test-data sheet bearing on the right a graph of the light distribution in a mean vertical plane about a source, and on the left corresponding zonal-flux values.

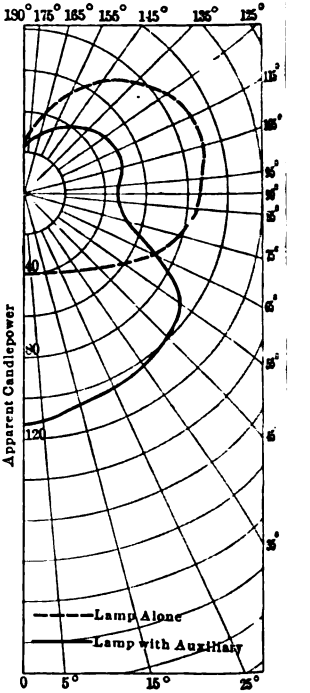

FIG. 44.—Photometric test sheet showing light distribution and values of intensity and flux.

**184. Spherical reduction factor.** In rating some types of illuminants, notably incandescent lamps, it has unfortunately been customary to adopt as a basis the mean flux density or candle-power in a horizontal plane through the source. Whether rated in this way or by the candle-power in some other direction or plane, it is always desirable to reduce the values to total light flux for some purposes. Hence reduction factors are commonly given with some illuminants, and the term, "spherical reduction factor," has come to be applied especially to the ratio between mean spherical candle-power and mean horizontal candle-power of incandescent electric lamps. (See Par. 80.)

## CALCULATIONS OF ILLUMINATION INTENSITY

**185. Classification of methods.** Assuming that light distribution data, uch as those presented in Fig. 44 are available, it becomes possible to com- ute the illumination produced upon any given plane by the light source in ny given location. For the sake of simplicity it will be considered that the ght source, whose distribution is indicated in the diagram, is mounted over he centre of a horizontal plane which is to be illuminated. For such com- utations there are three customary methods. The flux of light delivered pon the horizontal plane will be the sum of that directed toward the plane rom the source and that reflected to the plane from ceiling walls, etc.

**186. Flux method (direct light).** For many purposes an approximate alculation of the flux delivered upon the plane of reference is adequate. n such cases it may serve to determine the approximate square feet of the lane to be illuminated and to estimate the total flux which will reach such lane. For example, assume that a certain room has a floor area 12 ft. 7 in. y 12 ft. 2 in., and that it is desired to estimate the light flux delivered upon a orizontal plane 36 in. above the floor from a light source located over the entre of the area, and 6 ft. 4 in. above the plane of reference.* Roughly, the ux delivered within an angle of 45 deg. above the horizontal will fall upon his plane. Applying zonal constants (Par. 181) to the candle-power values n Fig. 44, we have either or both of the following:

| Angle | Constant c-p. | Angle | Constant c-p. |
|---|---|---|---|
| 40 | $0.383 \times 100 = 38.3$ | 45 | $0.295 \times 99 = 29.2$ |
| 30 | $0.297 \times 102 = 30.3$ | 30 | $0.446 \times 102 = 45.4$ |
| 20 | $0.203 \times 105 = 21.3$ | 15 | $0.230 \times 107 = 24.6$ |
| 10 | $0.104 \times 110 = 11.4$ | 0 | $0.029 \times 113 = 3.3$ |
| 0 | $0.013 \times 113 = 1.51$ | ..... | ..... |
| Mean zonal c-p.....102.81 | | Mean zonal c-p.....102.5 | |

With a mean candle-power of 103 distributed throughout a zone extending rom the nadir to 45 deg., the flux in lumens is found by multiplying 103 by he number of unit solid angles in the 45. deg. zone or $103 \times 2\pi (\cos \theta_0 - \cos \theta_{45}) = 190$ lumens.

**187. Flux method (indirect light).** Referring to report of test* of he installation described it will be seen that the lumens directed to the plane f reference by the lighting unit are 191 in number, with which value the bove determination is in accord. The light source produces 779 lumens. s 191 lumens reach the plane of reference (779 − 191 =) 588 are incident upon eiling and walls, where they are partly absorbed and partly reflected ither toward the plane of reference or elsewhere. The greatest uncertainty n estimating total flux on a plane is arriving at the amount of such indirect ght. The test* shows that 189 lumens or (189/588 =) 32 per cent. of this ux, which the lighting unit directed elsewhere, ultimately reached the plane f reference, thus equalling the light directed toward the plane by the lighting nit. In this case the room was small and the reflection from ceiling and alls was more effective than usual. If instead of a room the area is a bay in larger room, the light, which here falls upon the walls, will add to the illumi- ation of adjoining bays, and the bay under consideration will profit likewise rom adjoining bays. In any installation this indirect light must be esti- nated taking into consideration the flux directed elsewhere than upon the lane of reference and the reflecting qualities and location of the reflecting urfaces. Some data on this subject are given in Par. **186**.

## EFFICIENCY OF UTILIZATION

**188. Definition.** Where the illumination of such a plane is the principal urpose of the lighting installation, the ratio of flux delivered upon the plane o total flux produced by the illuminant is sometimes called the "efficiency of

* Actual conditions described by Sharp and Millar, "Illumination Tests," rans. Illg. Eng. Soc., 1910, p. 391.

Digitized by Google

utilization." In this case, assuming that the reflector used with the illuminant absorbs 20 per cent. of the total flux produced, there will be an efficiency of utilization of 376/(779/0.8) = 39 per cent.

**189. Estimates of efficiency of utilization.** In many cases where estimation of this character is undertaken, practitioners become so familiar with the effects produced that they do not take the trouble to separate direct from the indirect components of the light which reaches the plane of reference, but approximate a total ratio of flux upon the plane of reference to flux produced by the illumination. Such percentages usually range from 25 for indirect lighting systems, to 60 for the best direct lighting systems. Some figures furnished by Cravath are of interest in this connection.

**190. Ratio flux delivered upon 30-in. horizontal plane, to total flux produced by illuminant**

(*Deduct 25 to 50 per cent. for dirt, etc.*)

| | Dark | Light | 1–2.5 | 25–35 |

**191. Data on efficiency of utilization.** Sweet* has worked out very complete data upon the efficiency of utilization of light in small and medium sized rooms illuminated by Mazda lamps with reflectors selected to give approximations of uniform distribution of light over a horizontal plane 30 in. above the floor. His test room was 13 ft. 6 in. by 23 ft. 6 in. with a ceiling height 10 ft. 4 in. One side of the room was given over to window space; walls and ceiling surfaces were of mat white cardboard. His results, which are in part test data and in part values derived from test data by computation, are presented in Figs. 45 to 47, showing ratio of light delivered upon the plane of reference to total light produced by the illuminants with the light source over the centre of the room, with ceilings having respectively light-reflecting coefficients of 60, 40 and 20 per cent., and with wall-reflection coefficients as stated. Thus in Fig. 46, which presents data applicable to a 40 per cent. reflection ceiling, it will be observed that, with a light-density opal

* Illg. Eng. Soc., February 8, 1912.

Digitized by Google

eflector, 42 per cent. of the total light produced is delivered upon the plane f reference if the walls have reflection coefficients of 30 per cent., while 45 per ent. is delivered upon the plane if the reflection coefficients of the walls mount to 60 per cent. These very complete data should be helpful in forming a correct estimate of the net ratios of light utilization in small and edium sized rooms with central-ceiling equipments.

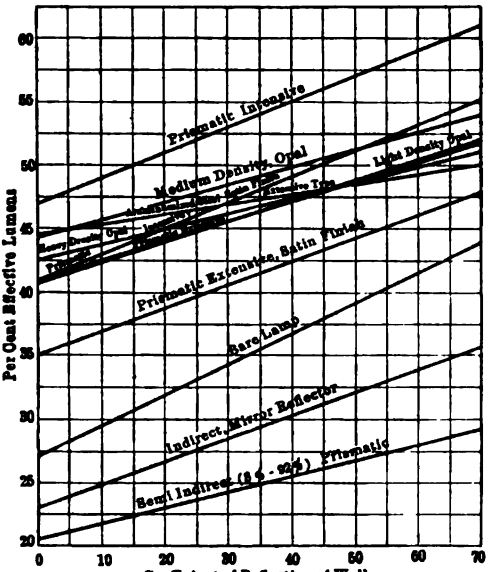

FIG. 45.—Per cent. flux delivered upon working plane when reflection coefficient of ceiling is 0.60.

**192. Influence of wall reflection on efficiency of utilization.** A study of these data of Sweet (Par. 191), indicates that with 60 per cent. ceilings the loss in flux on the plane of reference involved in changing from 40 per cent. to 10 per cent. reflection walls, ranges, for the several equipments, from 5 per cent., in the case of opaque reflectors where very little light is incident upon the walls, to a maximum of 20 per cent. in the case of a bare lamp. The details of these losses are given in Par. 194.

**193. Comment on flux method.** From the foregoing (Par. 189 to 192) a reasonably accurate estimate of the influence of ceiling and walls may be formed. As the flux directed toward the plane of reference by the lighting unit may be computed quite accurately where a light distribution curve is available, and as this direct lighting is usually the greatest proportion of the total which reaches such plane, it will be seen that estimates of the illumination produced may be made very quickly by this method, and will be usually as precise as conditions require. The computation of the angle below which all of the flux is directed toward the plane, is a simple matter of triangulation. Most recent light-distribution data are accompanied by zonal-flux data (Fig. 44) which makes the approximation of the total flux within the directly applied zone a mere matter of addition. Where zonal values are not available computation of the flux from the light distribution curve is reasonably simple (Par. 186).

**194. Reduction in flux on 30-in. horizontal plane involved in reducing reflection coefficient of walls from 40 to 10 per cent.**

(*Reflection coefficient of ceiling being taken as 60 per cent.—lamp over centre of room*)

| Lamp used with | Per cent. loss |
|---|---|
| Opaque reflector | 5 |
| Heavy-density opal (depolished) | 8 |
| Medium-density opal (high glaze) | 9 |
| Prismatic extensive | 10 |
| Light-density opal | 10 |
| Prismatic intensive | 11 |
| Prismatic intensive (satin finish) | 12 |
| Prismatic extensive (satin finish) | 13 |
| Semi-indirect | 15 |
| Indirect mirror reflector | 18 |
| Bare lamp | 20 |

**195. Flux to produce given illumination.** In many cases of illumination practice it is desirable to invert the order of computation and beginning with the flux density or foot-candles required upon the plane of reference, to determine by this method how much light flux must be produced. Taking the case assumed above (Par. **186**), and assuming further that an illumination intensity of 2.5 foot-candles or 2.5 lumens per sq. ft. is required, the area of the room, 153 sq. ft., is multiplied by 2.5, giving 382 lumens which should be applied upon the plane of reference. It may be assumed that this can be

Digitized by Google

accomplished by using a reflector which, while directing most of the light toward the plane, will still transmit sufficient to light the ceiling and walls acceptably. With such equipments it is reasonable to expect that 50 per cent. of the light may be delivered upon the plane of reference. At once it is established that 764 lumens should be generated within the room. This will be produced by a 100-watt Mazda lamp, which produces about 1,000 lumens, leaving a margin of 25 per cent. for absorption by reflector, depreciation due to dust, etc.

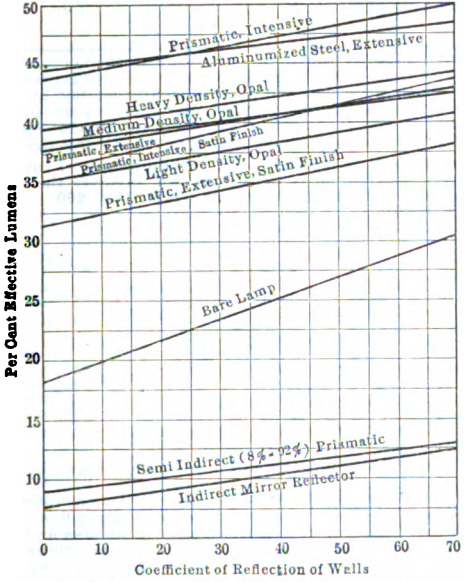

FIG. 47.—Per cent. flux delivered upon working plane when reflection coefficient of ceiling is 0.20.

**196. Absorption-of-light method.** An alternative method of computing light flux for an illumination installation is the "Absorption-of-light" method.* This is based upon the fundamental consideration that all of the light within a room being absorbed, the illuminants must produce the sum of the light flux absorbed by the various surfaces. That is to say, the average incident flux upon each surface multiplied by the coefficient of light absorption characteristic of that surface and by the area of the surface will yield the total flux absorbed by that surface, and the sum of the flux absorbed by all exposed surfaces within a room must aggregate the total flux to be produced by the lighting unit. (In such case, of course, the absorption of light involved in the use of an auxiliary must be added to this aggregate to ascertain the total amount of light to be produced by the illuminant proper.) Referring to the room already mentioned,† we find the data necessary to verify this method. These are summarized in Par. **197**.

**197. Absorption of light in a given room**

| Surface | Lumens | | |
|---|---|---|---|
| | Incident from all directions | Coefficient of absorption | Absorbed |
| Ceiling | 280 | 0.14 | 39 |
| Walls | 672 | 0.57 | 382 |
| 36-in. horisontal plane | 376 | 1.00 | 376 |
| Total | | | 797 |

**198. Point-by-point method.** The third method of computing illumination, the "point-by-point" method, is laborious but it is best calculated to yield results which are accurate in detail. By this method an exact computation is made of the intensity of light directed upon any surface by the lighting equipment, and to this is added an estimated amount for the diffused and indirectly reflected light which supplements the direct light.

**199. Illumination intensity.** The determination of intensity at any point when the distribution of light is known, involves the application of two fundamental laws, the inverse-square law (Par. 200) and Lambert's cosine law (Par. 201).

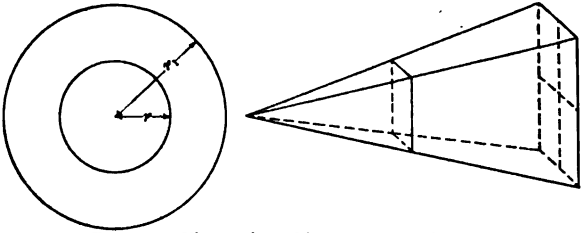

FIG. 48.—Illustration of inverse-square law.

**200. The inverse-square law (Par. 199)** is demonstrated in Fig. 48 in which it is apparent that at twice the distance the given flux of light radiating from a point source covers four times as great an area and therefore its density is one-quarter as great. Proof of this law is as follows: let $E$ = Intensity, in foot-candles; $F$ = Flux, in lumens; $S$ = Surface, in sq. ft.

$$E = \frac{F}{S} = \frac{F}{4\pi r^2} \tag{6}$$

$$E_1 = \frac{F}{4\pi r_1^2} \tag{7}$$

or

$$\frac{E}{E_1} = \frac{r_1^2}{r^2} \tag{8}$$

that is $E$ varies as $1/r^2$.

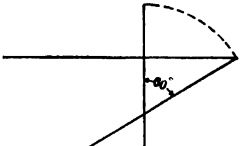

FIG. 49.—Illustration of cosine law.

**201. Lambert's cosine law (Par. 199).** If, however, the plane surface upon which the light falls is inclined from the normal, the flux of light incident upon the surface will vary as the Cos of its angle of inclination. This is known as Lambert's cosine law.

$$E = \frac{I \operatorname{Cos} \theta}{d^2} \tag{9}$$

where $I$ is the candle-power, $\theta$ is the angle of inclination to normal, and $d$ is the distance from source to surface. This reduction in incident flux due to inclination of the surface is illustrated in Fig. 49 in which it is seen that if the surface is inclined 60 deg. from the normal, the incident flux will be halved (Cos 60 deg. = 0.5).

**203. Computation of illumination intensity at any point.** In computing the illumination intensity or flux density upon any surface, the distance from the light source to the surface is computed, the candle-power is divided by the square of the distance in order to obtain the normal illumination intensity, which is multiplied by the Cosine of the angle of inclination of the surface in order to obtain the flux density or illumination intensity for any desired inclination.

$$E_{nor.} = \frac{I_\theta \operatorname{Cos}^2 \theta}{h^2} \quad \text{in ft.-candles or lumens per sq. ft.} \tag{10}$$

$$E_{hor.} = \frac{I_\theta \operatorname{Cos}^3 \theta}{h^2} \quad \text{in ft.-candles or lumens per sq. ft.} \tag{11}$$

$$E_{vert.} = \frac{I_\theta \operatorname{Cos}^2 \theta \sin \theta}{h^2} \quad \text{in ft.-candles or lumens per sq. ft.} \tag{12}$$

where $I_\theta$ is the candle-power at stated angle, $\theta$ is the angle from the vertical, and $h$ is the height in feet above plane of reference. In such computation, the distance is obtained by triangulation and the formula is such as to leave the $\operatorname{Cos}^3 \theta$ the significant factor for computations of horizontal illumination and the $\operatorname{Cos}^2 \theta$ for computations of vertical illumination. In Par. **202** are given values of $\operatorname{Cos}^2 \theta$ and of $\operatorname{Cos}^3 \theta$ which will be of service in this connection.

**204. Aids to computation of illumination.** A number of graphical and mechanical aids to the computation of illumination have been devised.*

## BRIGHTNESS

**205. Definition of brightness.** In Fig. 50 a diffusely reflecting surface which is uniformly illuminated, is viewed from position $P$ through an aper-

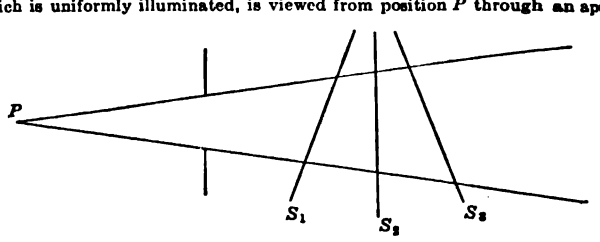

FIG. 50.—Illustrating brightness characteristic (Par. **205**).

ture in a screen. The surface is located successively in three positions $S$, $S_2$ and $S_3$. In all positions it appears of the same brightness. Its brightness is independent of inclination or distance from the eye. The brightness

f a surface which is not a perfect diffuser may vary with angle of view, but it is large enough to cover the field of view, its apparent brightness will not ary with distance.

**206. Relation of brightness to incident light.** This may be stated nly for a projected area of a perfectly diffusing plane surface for which $= mE$ where $b$ is the brightness; $m$ is the coefficient of diffuse reflection; nd $E$ is the incident flux. Brightness is expressed in candle-power per q. cm. or in candle-power per sq. in. Interiors as illuminated at night have rightness values of the order of 0.0005 candle-power per sq. cm.

## APPLIED ILLUMINATION

### THE FUNDAMENTALS OF VISION

**207. Contrast vision.** We see things by reason of contour, relief and olor, *i.e.*, shade perception and color perception. According to Fechner's aw of sensations we perceive a fixed fractional difference of the total, irrespective, within limits, of the amount of the total sensation, and the sensaion is proportional to the logarithm of the stimulus. This minimum perceptible contrast is usually of the order of 1 per cent., and, with increasing rightness within wide working limits, the visual power increases but slowly.

**208. Color sensations.** Ocular discernment as presented in the Young-Helmholtz theory is based upon three primary sensations: red, green and blue-

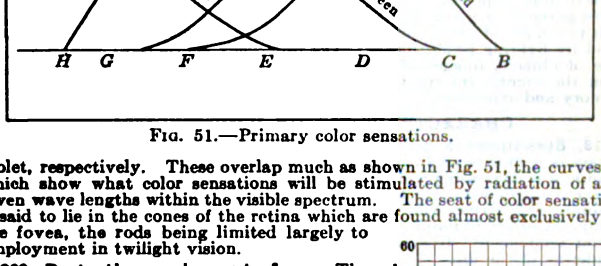

FIG. 51.—Primary color sensations.

violet, respectively. These overlap much as shown in Fig. 51, the curves of which show what color sensations will be stimulated by radiation of any given wave lengths within the visible spectrum. The seat of color sensation s said to lie in the cones of the retina which are found almost exclusively in the fovea, the rods being limited largely to employment in twilight vision.

**209. Protective equipment of eye.** The protective apparatus of the eye against excessive radiation, consists, first, of the **pupil**, whose automatic response to changes in intensity of light under certain conditions are shown* in Fig. 52. It will be seen that the area of the pupil aperture does not alter sufficiently to protect the eye against effects of the large changes in illumination which it must encounter; the second protective element is to be found in retinal adaptation.

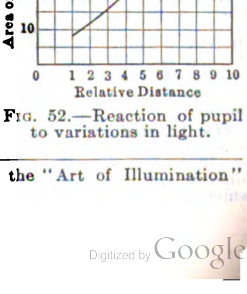

FIG. 52.—Reaction of pupil to variations in light.

**210. Other ocular characteristics.** Some of the physiological characteristics of the eye which are of importance in illumination work are as follows: (a) **adaptation**, the slow retinal change which supplements the rapid pupillary change both tending to adjust the eye

*Lambert's Experiments as reproduced in the "Art of Illumination" by Bell.

Digitized by Google

for best vision under any condition of light intensity; (b) **induction**, the name applied to that effect of contrast which causes a dark surface to appear darker when in juxtaposition with a brighter surface or *vice versa;* (c) **Purkinje effect**, the tendency of the eye to become more sensitive to light of short wave lengths than to light of long wave lengths when the intensity is low. Due to the last-mentioned effect, with the same low intensity of light blues and greens appear brighter than does red. See also Par. 10–12.

**211. Threshold vision.** In many ocular tests the point of minimum perception is the basis adopted. These are known as "threshold" or "limen" tests, and are applied to determine **visual acuity**, flicker, etc. Visual acuity is generally expressed in terms inversely proportional to the visual angle subtended by the observed object at threshold value, unity being taken as an angle of 5 min. Visual acuity is tested by determination of the smallest discernible object, as a letter, under a given low intensity of illumination; or the greatest distance at which a given object under a given intensity of illumination may be discerned; or the minimum illumination at which a given object at a given distance may be discerned. **Flicker tests** usually consist in the determination of the minimum change in intensity upon an observed object which may be perceived with a given rate of flicker, or the minimum rate of flicker which may be detected with a given change in intensity. Threshold tests of shade perception are also applied. The line of division between such tests and visual acuity tests is not clearly indicated, since some visual acuity tests in one sense are shade perception tests. In all such tests the accuracy attained is of a lower order than that attained in comparison tests where one surface is brought to the same brightness as another surface in juxtaposition to it.

**212. Psychology of vision.** Vision is a combined physiological and psychological process. For example, the eye as an optical instrument produces upon the retina an inverted image of an object viewed. This applies the stimulus to produce the sensation. The mind interprets before the object is rightly perceived. Therefore the subjective phenomena associated with vision are of prime importance; unfortunately they are but little understood by lighting practitioners. The observer's conception of the appearance of objects, images of which are impressed upon the retina, depends upon the mental interpretation of such images in the light of tradition, memory and experience.

## CHARACTERISTICS OF ILLUMINATION

**213. Steadiness vs. fluctuation in light.** Reliability in an illumination system is a first requisite. Of a like obvious character is steadiness. Unsteadiness is distressing and perhaps injurious to the eyes in spite of the protective features with which they are provided. Unsteadiness of light, as encountered in flames which fluctuate with atmospheric disturbances, is not found in electric illuminants as a rule, though arc-lamps exhibit somewhat similar tendencies. Unsystematic fluctuations in the arc may be due to a wandering of the arc. This propensity changes the light-distribution characteristics, notably in the open carbon-arc lamp; or results in vaporizing a more or less luminous material from the electrode, as in the flame-arc lamp and metallic-electrode lamp. Requirements in indoor lighting are such as to bar badly fluctuating light sources from general use. The requirements for exterior lighting are less rigorous in this respect, and therefore arc-lamp fluctuations which could not be tolerated for most indoor purposes, do not constitute serious objections for some classes of exterior lighting.

Incandescent lamps are subject to unsystematic light fluctuations only when operated upon a circuit which carries a varying power load as, for example, elevator motors. **Systematic light fluctuations** occur on alternating-current service. Incandescent lamps are characterized by greater thermal stability than arc-lamps, and these cyclic light fluctuations are therefore less serious. For incandescent lighting, 35 cycles appears to be the approximate lower frequency limit for satisfactory service of all classes, though for many purposes 25 cycles lighting has been found satisfactory.

**214. Intensity or flux density** is an all-important fundamental to be considered in illuminating practice. Sufficient intensity of light must be provided to serve utilitarian purposes, to enable the eyes to accomplish their function without undue fatigue, and to create pleasing effects—three purposes which must be served in the order of their importance in all installations. To

Digitized by Google

accomplish this it may be necessary to provide an illumination of uniform intensity, or the flux may have to be distributed dissymmetrically. Shadows are important, contrasts must be correct and a careful study of the intensities necessary to produce brightness of the right order is essential to success in lighting installations.

**215. Intensities for various classes of service.** For the more usual classes of work, intensities of illumination range from 1 to 7 foot-candles. In some classes, as in draughting rooms, 10 to 20 foot-candles are required. In other classes of lighting, very much higher values must be provided, notably in show-window lighting where the demand for great brilliancy fixes a standard of 25 or 30 foot-candles for general purposes and in industrial work, as in sewing upon dark garments where the work is done over limited areas, values as high as 100 foot-candles may be desirable. The standard to be set in any given installation must be reached after careful study of the local conditions and of the requirements peculiar to that installation. Pronouncements of various writers on this subject are of value in serving as a general guide, but they should not be regarded as final for any particular installation. A compilation of published data on intensities is presented in Par. **219**.

**216. Direction.** The best direction for the strongest component in any illumination system is peculiarly a matter for determination after study of local conditions. In natural lighting there is usually a strongly directed component, the only exception being a condition of diffused light such as that produced by mists, rain, etc. A great variety of directions for this principal component is experienced, ranging from one almost directly downward at mid-day in the summer to one which is almost horisontal just after sunrise or just before sunset. It is probable that the most pleasing direction for daylight conditions lies well between these two extremes.* The direction of light in interiors illuminated from side windows is unnatural and in many instances is neither pleasing nor comfortable. This is especially true of offices in high buildings where nothing but the sky is visible through the window from a point well in the interior of the room.

**217. Direction of light affects appearance.** A suitable direction for light is very important in industrial work where the avoidance of shadows and the avoidance of glare are of paramount importance. The appearance of a room is very largely dependent upon the direction of the light.† In ornamentation, relief designs are absolutely dependent upon the relation of light and shade.‡ Usually they require not only a noticeable directed component but also they require that the direction of that component shall be correct. So also, in the general appearance of a room and of the objects contained in it, shadows are important and their proper direction is a prominent factor in determining the final appearance of the room. The direction of incident light is, to some extent, a determining factor in the extent and characteristic of the reflection from surfaces.‖

**218. Diffusion.** See Par. **220**. If light from a point source passes through crystal glass or is reflected by a mirror, the rays are uniformly divergent, that is characteristically radiating. If the crystal glass or the mirror be replaced by an etched glass and a mat reflecting surface respectively, the uniform radiating characteristic is lost, the rays are scattered, and further propagation takes place in a multiplicity of directions. Such light is called diffused light. If the surface which occasions the diffusion is of large area and the illuminated object is relatively close to the diffusing surface, it is illuminated by diffused light. If, however, the object is relatively far removed from the diffusing surface, it is illuminated by light from essentially one direction, the rays are nearly parallel, and the light is but little diffused. Hence, diffusion is a relative term, and the subject is difficult to treat in a definite way.

**220. Various degrees of diffusion.** See Par. **218**. Perfect diffusion of light is obtained within a hollow sphere whose inner reflecting surface is mat. Some plane-reflecting surfaces are nearly, if not quite, perfect diffusers of light. Perfect diffusion may be represented graphically by a circle, tangent upon the diffusing surface. Imperfectly diffused transmission or reflection may be represented by various curves having radials elongated in the direction of regular transmission and reflection, indicating correspondingly lesser distribution in other directions than is provided by perfect diffusion.* A variety of reflection characteristics is illustrated in Fig. 53, ranging from perfect diffusion to a combination of regular and diffuse reflection characteristic of glossy paper.

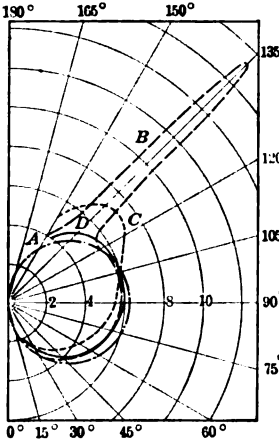

FIG. 53.—Various degrees of diffuse reflection. Light incident 45 deg. below horizontal, surface being vertical. A, perfect diffusion; B, reflection from glossy paper; C, reflection from semi-glossy paper; D, reflection from mat paper.

**221. Need for diffusion.** Diffusion tends to avoid glare and to soften shadows. Its accomplishment involves the substitution of secondary light sources which are relatively large and therefore of low brightness when compared with the source of light. Artificial lighting is usually inferior to natural light in respect to diffusion.† In practically every installation there is a real necessity for introducing artificial means of diffusing the light.

**222. Color** in its physical aspects has been treated in the discussion of the production of light (Par. **27**). The spectrophotometric values of light from the several common illuminants have been supplemented by color-sensation values as determined with color-mixing instruments. Referring further to the subject in its physiological relations, it may be noted that there are three primary colors, namely: red, green, and blue-violet, using pure spectral light. With these three colors, light of any desired color value may be produced. In his ability to modify the color of light, the illuminating engineer has at his disposal a means of enhancing the attractiveness of an interior as will be brought out more in detail under discussion of congruity in illumination, Par. **232**. It also is a field in which there is an opportunity for profiting by certain peculiarities of vision (Par. **208**).

## PHYSIOLOGICAL AND PSYCHOLOGICAL EFFECTS OF ILLUMINATION

**223. Contrast.** Once the correct general intensity of light (Par. **216**) is secured, all other aspects involved in direction (Par. **217**), diffusion (Par. **218**) and color (Par. **222**) as well as in the distribution of the light to produce various intensities, must be so manipulated as to secure the proper degrees of contrast. The more the subject of good illumination is considered, the more prominently does contrast force itself upon attention as a fundamental which must be served if an installation is to be successful. This applies both to contrast of light and shade and to contrast of color. Contrast of light and shade resolves itself into a question of varying brightness, embracing the range of brightness values from a brilliant incandescent-lamp filament or an arc, down to the deepest shades within view. The unshaded

* Nutting. "The Diffuse Reflection and Transmission of Light," *Transactions* Illg. Eng. Soc., 1912.

† Luckiesh. "Investigation of Diffusing Glassware," *Electrical World*, Nov. 16, 1912 and April 26, 1913.

Digitized by Google

incandescent lamp glowing outdoors in the daytime does not appear very bright against a background of sky, and may be viewed directly without discomfort. The same unshaded lamp burned at night in a room which is decorated in light colors, will prove annoying, while if burned in a room of which the decorations are of low reflecting quality, as dark woodwork, the lamp will prove positively intolerable. In the three cases the brightness of the lamp remains the same, and it is the varying contrast with its surroundings which explains in the one case, absence of discomfort and in the other extreme case, the most serious kind of ocular discomfort.

**224. Need for concealing light sources.** In Par. 31 brightness values for various unshaded light sources are given. It will be observed, for example, that these range from less than one candle-power per sq. in. for the Moore tube to 4,000 candle-power per sq. in. for the magnetite arc. This is, indeed, a wide range in brightness. When, however, it is remembered that the brightness of a very well-lighted wall, decorated in some light tone is of the order of 0.003 candle-power per sq. in., it will be seen that the variations in brightness of commercial light sources are small in comparison with the contrasts between any of them and the surfaces with which they are likely to be surrounded in practice. Herein lies the necessity for shading light sources in order to protect the eye against excessive contrasts. Entirely capable of protecting itself against excessive brightness, the eye is not able to see the objects of relatively low brightness and at the same time guard itself against the very high brilliancy of an exposed light source. There still remains the necessity for avoiding the intrusion of reflected images of the light sources in the ordinary field of view. A well-shielded light source may be exposed in the direction of a polished table top, the surface of which may reflect an image of the light source, subjecting the eye to almost as great strain as though the actual source were exposed. Glossy paper, shiny materials to be worked upon, polished woodwork, etc., are likely to introduce this sort of difficulty. Nature's surfaces as a rule are not shiny; artificial surfaces are likely to be shiny. In abolishing glossy paper, polished woodwork, etc., a long step is taken toward the elimination of excessive contrasts in artificial lighting. It is not possible, however, to abolish all such surfaces, and in other cases it is not done. It is, therefore, desirable to conceal the light source further. Accordingly, the improvement of a few years since in providing translucent reflectors which largely cover incandescent lamps and shield them from direct view, has been supplemented more recently by frosting the lower part of the bulbs of the lamps and the interior surfaces of the reflectors in order to soften and diffuse the light. Consequently, when reflected images are encountered, their brightness is rendered of as low an order as practicable. More recently still, bowls have been employed, either opaque or translucent, which intervene between any point of observation and the light source proper, softening and diffusing the light and directing a part or all of it toward the ceiling, whence it is further diffused and reflected downward.

**225. Glare due to light source.** Excessive brightness of surfaces or objects within the field of view gives rise to glare. Where the light source itself is within view, or a more or less imperfect image is viewed upon some shiny surface, the effect is much the same and is a manifestation of the same difficulty, namely excess of contrast (Par. 223). Glare or excess of contrast may actually reduce one's visual power temporarily; it may occasion discomfort and eye-strain; or, if continued long enough, may seriously impair visual organs. In the way of reduction in visual power, observations have been made of the extent of the effect.* Such studies are so complicated and difficult that definite results can be obtained only under very extreme conditions. In Fig. 54 is shown the reduction in visual power due to the presence of an exposed lamp in a dark room. The observers viewed a dimly illuminated test object. The presence of a 16-candle-power bare lamp 2 deg. from the test object, reduced the observers' ability to discern the test object to about the same extent as would follow a reduction in the illumination to 20 per cent. of that which was provided. As the light source was placed more and more distant from the observed object, its influence became less marked, falling off rapidly until the angle of separation was 4 deg. and thereafter at a slower rate until, at about 15 deg., the

*Sweet. "An Analysis of Illumination Requirements in Street Lighting," Journal of the Franklin Institute, May, 1910.

Digitized by Google

effect disappeared. Because of the very exaggerated conditions of dark surroundings and dimly illuminated test object, the results here obtained show diminished visual power far beyond that which would likely be experienced in practice. They illustrate the effect, however, and are suggestive of the need for concealing the light source. It is to be noted that, though no reduction in visual ability could be measured when the source was removed 15 deg. from the centre of the field of view, yet the discomfort and annoyance due to its presence were very severe.

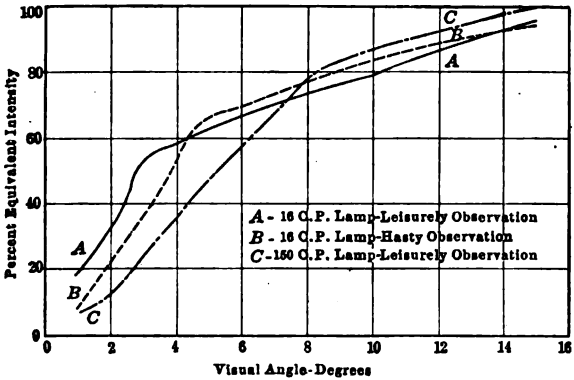

FIG. 54.—Influence of glaring light source in decreasing visual power.

**226. Glare due to reflected image of light source.** Glare due to images of light sources reflected from shiny surfaces is probably more productive of harm in the present stage of practice than is glare directly due to exposed light sources. While the imperfect rendering of the image by the usual polished surfaces decreases the brightness materially, yet the location of the reflected image is often so near the centre of the field of vision as to be much more serious than an exposed light source further removed. Viewing a glossy paper at the critical angle in which the image of the light source is reflected to the eye, it may be impossible to read print. This effect is diminished by altering the position of the object or of the observer, but, due to minute irregularities of the surface of the paper, there is still likely to be an appreciable regular reflection toward the eye. Likewise, paper which is only slightly glossy may reflect regularly toward the eye an appreciable section of the image of the light source without introducing so serious an effect as to prompt the observer to change position. Such conditions are the source of much discomfort and dissatisfaction experienced in artificial lighting. If they are to be avoided, light sources must be shielded both from immediate observation and from possibilities of reflection from glossy surfaces.

**227. Coefficients of reflection.** If it be assumed that softly diffused light is distributed generally throughout an interior producing uniform illumination, contrasts are dependent wholly upon the reflecting qualities of the illuminated surfaces. As these are usually less readily changed than the distribution and quality of the light, it is desirable to consider them before determining upon the degree of uniformity which should be achieved in light distribution. Uniform illumination with uniform decorations in an interior would be undesirable from every standpoint. Uniform illumination with heavily contrasted decorations and fittings may be acceptable. It is therefore of interest and value to obtain information on the coefficients of reflections of various surfaces, such are contained in Par. 228.

**229. Shadows.** Further contrasts are encountered in shadows. The more generally the light is distributed, the lighter are the shadows; the more generally the light is diffused, the less sharp are the shadow contours. Both depth of shadow and sharpness of outline are of importance in contributing to the effect of contrast. When properly treated, relatively deep shadows are of importance in contributing to perspective and in producing a satisfying effect. In some kinds of industrial work, in office work and in some other classes of work all but very soft shadows should be avoided. Rolph† has concluded that for working surfaces when the shadow has sharply defined outline, it should not be more marked than 15 per cent., while if the outline is quite indefinite, as with well-diffused lighting, it may be as much as 50 per cent.

**230. Color contrast.** The remaining aspect of contrast is the important one of color. Pleasing color contrasts are of value in affording rest for the eye, in lending perspective, and in preventing monotonous effects. The color effect of a given surface depends to no little extent upon the color of other surfaces in the field of view with which it is contrasted. Also, very slight modifications of the light may produce marked changes in the appearance of the colored surfaces. The choice of the correct color for the light employed in a particular case is therefore essential to successful illumination from the decorative standpoint.

**231. Permissible contrasts.** In general, authorities state that bright objects to which the eye is subjected should not exceed 4 or 5 c-p. per sq. in. (0.62 to 0.78 c-p. per sq. cm.) if physiological requirements are to be met. This applies to interiors at night. The limitation is relative rather than absolute. One authority,* while asserting the impracticability of fixing any standard, suggests that if the brightness of the object upon which the eyes are employed is of the order of 10 times that of surrounding objects, physiological requirements will be met satisfactorily.

**232. Congruity.** The requirements of esthetics are for illumination and an illuminating equipment which shall be pleasing to the senses and in harmony with the character of the premises illuminated. In buildings of notable architectural design the equipment should not only be suitable for its surroundings but the illumination should produce such combinations of light and shade, such contrasts, such color effects as will bring out in true proportions the important architectural features of the building, and will render its ornamentation in the manner conceived by the architect. In churches the illuminating equipment and the illumination must be of a character which is in keeping with the religious purposes for which the building is designed. In manufacturing establishments, effective illumination should be provided from simple, practical equipments. Incongruity of fixture, auxiliary, or illuminant; or unsuitability of light in quality, intensity, direction, etc., may mar an otherwise efficient illuminating system.

**233. Pigmentary colors.** Color of light, like color in decoration, is an aspect which affords many opportunities for skillful use by the illuminating engineer. In pigments, red, yellow, and blue of certain kinds and in certain proportions will produce white or any other desired color. They are sometimes referred to, therefore, as the primary colors, though, in a scientific sense, pure prismatic colors, respectively, red, green, and blue-violet, are the primary colors. The colors used for decoration are, however, dependent for their appearance upon the quality of the light by which they are illuminated.

It will be obvious, of course, that pigments which appear to the eye similar as regards color may be quite different physically, and that therefore their rendering under light of various colors may be markedly different from that here indicated. This is a field of application in which nothing may be taken for granted; only by trial can the appearance of a given pigment under a given light be determined. In decoration, therefore, a knowledge of the quality of the light employed is of first importance. It is essential that light be provided of such color value as will produce the effect desired in decoration.

**234. Ultra-violet light.** Some alarm has been felt by physiologists lest ultra-violet light from our ordinary illuminants should prove harmful to the visual organs. It appears to be quite clear, however, that nothing of this kind is to be feared. Recent investigations† show that little is to be apprehended on this score. The ultra-violet radiation from commercial illuminants is shown in Par. **235**.

The data in this table arrange illuminants according to their ultra-violet, radiation. Luckiesh, studying the same subject at about the same time, arrived at the following conclusion:

"It appears that when glass is used over any commercial light source there can be very little harmful effect when moderate intensities are used. Considering the greater intensities of daylight, protection, if necessary in any case, is really needed against it rather than against artificial illuminants except in the case of special use of the latter light sources."

## METHODS OF ILLUMINATION

**236. Direct lighting.** The fact that light sources are usually placed higher than the surfaces to be illuminated and that a downward direction of the light is rather generally desirable under such conditions, has led to the

| Carbon arc (quarts) | 91.0 |

common use of inverted-bowl or cone-shaped reflectors. These have been discussed at length in Par. 131 of this section. The fact that much of the light of such equipments is reflected toward the objects to be illuminated without the interposition of reflecting or transmitting media, has led to the adoption of the term "direct lighting" for installations so equipped. The employment of direct-lighting equipments usually facilitates the delivery of a maximum percentage of the total light upon the surfaces to be illuminated. So important has it been considered to promote this end, that the term "efficiency of utilization" (Par. 133) has sometimes been applied to the ratio of light delivered upon a working plane to total light produced within a room. This term has sometimes been applied to such ratios in installations where the importance of illuminating other surfaces is as great or greater than that of illuminating a working plane. Such misuse of the ratio of light delivered upon the working plane to light generated has brought it into disrepute, which has been the greater because of occasional application of the term "illuminating efficiency." This term is especially inappropriate by reason of the fact that other considerations than intensity of light have come to be regarded as of perhaps equal importance, though they are disregarded in arriving at the "illuminating efficiency" by the method indicated above. The ratio of utilization, or the per cent. of light flux delivered upon a working plane, other things being equal, is greater when direct-lighting equipment is employed than under other circumstances. It is more difficult, however, to obtain that degree of diffusion of light which is essential to the avoidance of glare and the elimination of excessively deep shadows. Direct-lighting equipment does not always yield, therefore, the most effective illumination obtainable from a given amount of light produced within a room.

**237. Indirect lighting.** Some of the worst difficulties encountered in the use of direct-lighting equipments were eliminated by the use of so-called "indirect-lighting equipments," in which the light sources are entirely concealed from view and the light is directed upon a reflecting surface such as the ceiling, which reflects and diffuses it. The reflecting surface in such systems becomes the apparent light source, and, being of large area, its brightness is very much lower than that of the real source. In consequence, shadows are softened, immediate glare effect is much diminished, and glare due to reflection from specular surfaces is likewise diminished. Indirect-lighting equipments produce conditions which are much more conducive to comfortable vision than are those usually attending the use of direct-lighting equipments. It is, however, much more difficult to control the light, and a much greater portion of the light is usually lost before becoming effective.

**238. Semi-indirect lighting.** Equipments intermediate between these two in respect to effectiveness of light direction, diffusion of light, softening of shadows and reduction of glare, have been classed broadly as "semi-indirect lighting" equipments. These consist usually of translucent bowls, translucency varying widely and brightness of bowl varying in a corresponding manner. In point of fact there is very little difference between lighting effects obtained with some indirect-lighting equipments and some semi-indirect lighting equipments because, in both, large proportions of the light are directed toward the ceiling, whence they are diffused throughout the

Digitized by Google

room. Enclosing globes also are likely to produce results of much the same order. When the translucency of the semi-indirect bowl is so low that its brightness of transmitted light is not greater than that of the ceiling, the lighting effects are likely to be quite similar to those which obtain when indirect-lighting fixtures are employed.

**239. Intermediate types of lighting equipment.** In brief, opaque reflectors which allow little light to be distributed elsewhere than upon the working plane are distinctively direct-lighting equipments and form one extreme of a range upon the other extreme of which indirect-lighting equipments may be placed. Between these two extremes are a great variety of equipments, all of which distribute part of the light upon the ceiling and part of it downward. It is difficult to differentiate among these intermediate equipments from the standpoint of illuminating results. Most such equipments, however, may be located in one of three classes, namely: (a) inverted bowls or cones; (b) totally enclosing glassware; (c) translucent bowls.

**240. Local illumination.** The tendency in recent years has been to depend upon general lighting as far as possible and to supplement it by local illumination only where unavoidable. It is well to do so because with local illumination it is difficult to avoid glare either from the source directly or from the illuminated surface. When, however, it is necessary to illuminate locally some surface, which must be very brightly lighted, every precaution should be taken to avoid the evils just named. The application of diffusing media and care in locating the light source will go far toward accomplishing this; and satisfaction is doubly assured if, in addition, there is an ample general illumination supplementing the local illumination.

## ILLUMINATION DESIGN

**241. The purpose to be served.** In laying out an installation a first step—so simple and obvious that its mention might appear unnecessary—is to determine the purposes to be served by the lighting installation. Usually one does not simply "light a room." He provides lighting in order to make a store attractive to the prospective customer and to promote the sale of goods; to illuminate the work on the machine and promote its prompt, accurate and safe accomplishment; to facilitate clerical work, promoting speed and accuracy without fatigue to the clerks; or to enhance the beauty and charm of a room in a residence. As a rule there are two or more principal objects to be attained in every installation. And the practitioner who familiarises himself thoroughly with the conditions underlying the requirements established by these objects takes the first essential step in successful lighting design.

**242. Choice of illuminant.** Usually general conditions narrow the choice to two or three illuminants. In a residence any other illuminant than incandescent lamps would be unsuitable. In a steel mill the choice would probably be narrowed to Type C Mazda lamps and flame arc lamps. In a store either Mazda lamps or intensified carbon arc lamps would be employed, etc. In a street either magnetite or Type C Mazda lamps would probably be considered. Reliability, simplicity, efficiency, color of light, steadiness, cost (first, operating and maintenance) and size usually determine this choice.

**243. Choice of auxiliary.** Cost, ease of cleaning, ruggedness, efficiency new and maintained, light-directing qualities, diffusion, color, size and appearance have to be considered. Obviously, the importance of each qualification depends upon the nature of the installation.

**244. Spacing and height.** In industrial and commercial lighting it is generally considered that the spacing should be something like 50 per cent. greater than the vertical distance from the plane of illumination to the light source. This is a sufficiently good relation to form a point of departure in planning an installation. In large rooms it is useful to divide the floor area into squares or approximate squares. Desirable sizes of these squares are given in Par. 245.* One light source may be placed over the middle of each such square. Often, however, the squares or rectangles which form the unit of space to be lighted are established by the confines of the room or by the pillars or beams which make the division of the room into bays. In such cases it may be practicable to treat the space as a unit or it may be necessary

*"Handbook on Incandescent Lamp Illumination," General Elec. Co., 1913.

Digitized by Google

to subdivide it into say four rectangles. Where uniformity of illumination or a distinctly downward direction for the light is desired, smaller rectangles should be adopted. Other things being equal, smaller rectangles should be used for direct lighting and larger ones for indirect lighting because in the latter case, the actual light source (ceiling) is higher and the diffusion is greater. In general, the adoption of smaller rectangles, which means more frequently spaced smaller light sources, results in greater uniformity less marked shadows and less glare, while larger rectangles and larger illuminants afford more pleasing appearance. Balance between these two depends upon local conditions.

**245. Desirable sizes of squares**

| Kind of room | Ceiling height | Desirable length of side of square |
|---|---|---|
| Armories | 12 to 16 ft. | 12 to 16 ft. |
| Auditoriums | 12 to 16 ft. | 12 to 16 ft. |
| Public halls | Over 16 ft. | 15 to 26 ft. |
| Rinks | Over 16 ft. | 15 to 26 ft. |
| Stores | 8 to 11 ft. | 8 to 11 ft. |
| Stores | 11 to 15 ft. | 10 to 16 ft. |
| Stores | Over 15 ft. | 14 to 22 ft. |
| Offices—with desk lights | 10 to 20 ft. | 12 to 18 ft. |
| Offices—without desk lights | 9 to 12 ft. | 7 to 11 ft. |
| Offices—without desk lights | 12 to 16 ft. | 9 to 14 ft. |
| Offices—without desk lights | Over 16 ft. | 11 to 18 ft. |

**246. Amount of light to be provided.** Assume that it is desired to light a room which is 20 by 12.5 ft. and 12 ft. high. The ceiling is white and the walls are buff. An average horizontal illumination of 4 foot-candles or lumens per sq. ft. is desired. Under such conditions it is reasonable to estimate that 50 per cent. of the light flux produced in the room can be delivered upon a horizontal plane with sufficient diffusion for most purposes, and with ample light upon ceiling and walls. About 30 per cent. should be allowed for deterioration due to dust, etc. Therefore the light to be delivered upon the 30-in. horizontal plane is to be considered as about 35 per cent. of the total light to be produced. The area of the room is 250 sq. ft. (20 by 12.5 ft.). This multiplied by 4 foot-candles, or lumens per sq. ft., yields 1,000 lumens, which, being 35 per cent. of the total to be produced, gives 2,860 lumens as an approximation of the total flux required.

A check upon the correctness of this estimate is had by the absorption of light method (Par. **196**).

| Surface | Area | Estimated average foot-candles | Estimated coefficient of absorption | Lumens Absorbed |
|---|---|---|---|---|
| Ceiling | 250 sq. ft. | 1 | 0.3 | 75 |
| Walls | 780 sq. ft. | 1½ | 0.6 | 702 |
| Floor | 250 sq. ft. | 4 | 0.9 | 900 |
| Total | | | | 1,677 |
| Allowance for 20 per cent. loss in reflector | | | | 419 |
| Allowance for 30 per cent. deterioration | | | | 898 |
| Total | | | | 2,994 |

As Mazda lamps produce about 10 lumens per watt it would appear that the required illumination could be obtained in the hypothetical room from either three 100-watt or two 150-watt lamps. To permit symmetrical arrangement the latter would probably be chosen and would be installed, each over the middle of a 10-ft. rectangle with a separation of 10 ft. If a plane of reference be chosen as 30 in. above the floor and the lamps be mounted 9 to 10 ft. above the floor, no difficulty will be met in selecting translucent reflectors whose light distribution will provide substantially uniform illumination over the plane selected. To study in detail the curve of illu-

Digitized by Google

ination to be obtained apply methods of point to point calculation as scribed in Par. 198 and add a uniform increase of, say, 10 per cent. of the verage, to represent the light reflected from ceiling and walls.

**247. Illumination of several classes of installations.** No attempt an be made here to discuss the special design features of the several classes of ghting installation. Those interested in the subject are referred to the ransactions of the Illuminating Engineering Society and to the technical ress for descriptive articles. An index to some of the more important ar-cles which may be consulted in this connection, is given in Par. 250.

## COSTS

**248. Calculation of total operating cost.*** "In determining the total perating cost of any system of lighting, three items should be considered: a) fixed charges, which include interest on the investment, insurance and axes, depreciation of permanent parts, regular attendance, and other xpenses which are independent of the number of hours of use; (b) mainte-ance charges, which include renewal of parts, labor, and all costs, except the ost of energy, which depend upon the hours of burning; (c) the cost of nergy, which depends upon the hours of burning and the rate charged.

"If data are compiled under these heads in convenient units, such as in a) an annual charge, in (b) a charge per 1,000 hr. operation, and in (c) charge per 1,000 hr. operation at unit cost of energy, the several items ay easily be calculated for any given set of conditions, and the total annual perating cost of any lighting system obtained as their sum.

"Under fixed charges, the items of depreciation and attendance may be entioned particularly. Depreciation should be charged on permanent arts only, and not upon parts the renewal of which is provided for in the aintenance cost. The rate for depreciation should, in many cases, be igher than the current practice, for obsolescence, rather than the wearing out f parts, determines the life of a lighting system. There are many installa-ions in use to-day which are in good order and giving a fair measure of satis-action, but which could be replaced at a large saving.

"Too much emphasis cannot be given to the desirability of regular attend-nce for those illuminants which do not require trimming from time to time. t is essential for satisfactory operation that such lamps and reflectors be leaned at regular intervals, hence a fixed charge should always be included or this service. Lamps which require frequent trimming are cleaned at the ame time, and the cost is included under the maintenance charge.

"The energy cost can usually be readily computed, but will, in the case of ome electric illuminants, depend upon the voltage of the circuit, since this etermines either the wattage or the power-factor. The effect of power-fac-or is seldom considered, although it governs the investment in generators, ransformers, and wiring, and, in a small degree, energy required. To the entral station or isolated plant, the volt-amperes required by a given lamp re perhaps as close a measure of the cost of service as the actual wattage onsumed. When the consumer is purchasing energy on a kilowatt-hour asis this factor, of course, is eliminated so far as he is concerned."

Principles of cost accounting in illumination may be laid down and with iscriminating application may serve to yield correct cost values. So largely, owever, are costs in lighting dependent upon local conditions, and so greatly o these conditions vary, that it is unsafe to apply in one installation cost ata obtained somewhere else, unless the differences in condition are first onsidered and allowance is made in the data for differences in such condi-ions. But little in the way of reliable impartial cost data has been published.

**249. Cost of light in relation to other expenses.** The total cost of rtificial light as a part of the cost of living or as a part of the total cost of peration of a business enterprise is very small. In 1912 the Department of Commerce and Labor in a bulletin entitled "Retail Prices 1890 to 1911" hows that as an average of 2,567 workingmen's families in 1901, the average ost of lighting per annum was $8.15 out of a total cost of $768.54, or 1.06 er cent. expended in lighting. The report of the Commission of Labor for 903, as presented at the 58th Congress, offers statistics compiled from the xpenditures of 11,156 workingmen's families; these show that the cost of

lighting in workingmen's homes averaged then 1.13 per cent. The average for any group, in a classification according to wages earned, was found not to depart from this value to any great extent.

**251. Proportion of lighting costs to total operating costs.** (1913)

| Class of lighting installation | Approximate cost of artificial lighting in proportion to total operating costs |
|---|---|
| Small wage-earner's home—ratio of cost of lighting to total income | 1 per cent. |
| Well-conducted large manufacturing establishments which are well lighted with modern illuminants—ratio of cost of artificial lighting to total cost of output exclusive of selling expenses | ½ to ¾ of 1 per cent. |
| Large retail mercantile establishments—ratio of total lighting cost to total sales | Probably less than 1.0 per cent. |
| Small stores—ratio of total lighting cost to total sales | 2 per cent. |
| Modern loft buildings | 1 to 2 per cent. |
| Street lighting appropriations by municipalities are of the order of 60 cents to $1 per inhabitant per year. | |

## PHOTOMETRY

### FUNDAMENTAL PRINCIPLES

**252. Disappearance or discrimination photometers.** Various photometers have been devised based upon determination of the threshold of vision. Some involve the discrimination of fine detail and are known as **visual-acuity** photometers. A well-known example is the "illuminometer" or reading distance instrument, which has been employed to some extent for street-lighting work. In this instrument the criterion is the maximum distance from the light source at which a given fine print may be read or the size of print which may be deciphered at a given distance from a light source. In another type the criterion is the perception of a given contrast, and may involve either the adjustment of the contrast for disappearance or the adjustment of the illumination for disappearance of contrast. An example of this is the "illuminometer" of Kennelly and Houston.* Still a third type of disappearance photometer has, as a criterion, the minimum perceptible flicker, and involves adjustment of the rate of flicker to determine disappearance or adjustment of the illumination to determine disappearance of flicker. These several types of photometers and others involving, in a modified form, the application of the same principles, are impracticable for measurement of illumination because, like any threshold or limen test apparatus, they are subject to errors which are ocular or mental in origin and are of an order so great as to make the instruments useless as photometers. These errors may be reduced by circumscribing the use of the instrument with precautions which limit the physiological variables. Even when the utmost precautions are taken, errors of the order of 25 per cent. are to be expected. It is sometimes asserted that discrimination photometers are to be looked to for the ultimate determination of illuminating value. This has not been demonstrated however. The true field for such apparatus and one in which their utility is considerable, is in the study of vision.

**253. Physical laws underlying photometry.** Regarded as a physical measurement, photometry rests upon the application of the law that light from a point source varies inversely as the square of the distance (Par. 200)

* *Electrical World*, March 9, 1895.

Digitized by Google

and that the illumination of a plane surface varies as the cosine of the angle of inclination to the incident ray (Par. **201**). These laws must be applied with discrimination and with strict regard for their practical limitations. The inverse-square law holds good only when the light source is relatively small with reference to the distance from the source to the illuminated surface. If the distance is less than five times the maximum dimension of the source, material divergence from the inverse-square law will result. The law may not hold good for relatively short distances when reflecting or refracting devices are employed to concentrate the light in a particular direction, as, for example, when a parabolic reflector is employed with an incandescent lamp or, as a more extreme example, a search-light. The cosine law applies to any plane surface insofar as the incident light is concerned. In many cases, however, the incident light is judged by the reflected or the refracted light. In such applications, the cosine law holds good only if the surface is a true diffusing surface, altogether free from regular reflection characteristics.

**254. Ocular characteristics affecting photometry.** In the comparison of lights of similar color, the process is not unlike other physical measurements since visual peculiarities do not affect the result. In heterochromatic photometry, in which lights of different colors are compared, ocular characteristics must be borne in mind, and the measurements must be carried out with due regard to the requirements which they impose. The three characteristics of greatest importance are as follows: (a) the Purkinje effect (Par. **255**); (b) yellow-spot vision (Par. **256**); (c) partial color blindness (Par. **257**).

**255. The Purkinje effect** is the name applied to the greater sensibility of the human eye to blue and green light at very low intensities than to red or yellow light. In accordance with this characteristic, if a mercury-vapor lamp is adjudged equal in illuminating power to a tungsten-filament lamp when the two are compared at a distance of 10 ft., the mercury-vapor lamp would be adjudged of higher illuminating power than the tungsten lamp if the comparison were to be made at a great distance.

**256. Yellow-spot vision.** The central portion of the retina of the eye, the yellow spot, comprehends a visual angle of 6 to 8 deg., throughout which the eye is less sensitive to green and blue light than is the surrounding portion of the retina. If a comparison of a mercury-vapor lamp and a tungsten lamp of equal power were to be made upon a surface so small as to fall within a visual angle of 6 deg., the mercury-vapor lamp would be adjudged of lower illuminating power than the tungsten. While a relatively higher evaluation would be accorded the mercury-vapor lamp if the illuminated surface were to be enlarged so as to comprehend a visual angle of say 24 deg.

**257. Partial color blindness** is often encountered. Eyes of certain individuals are found to be less sensitive to light of a given color than are normal eyes. The characteristic sensibility of the eye to light of different colors and of a given intensity when plotted diagrammatically is known as the luminosity curve* (Par. **10**). If an observer's sensibility to red is low, as shown by the luminosity curve for his eye, he would, of course, adjudge the illuminating power of a mercury-vapor lamp to be relatively high as compared with that of a tungsten lamp.

**258. Psychology in photometry.** In all photometry and especially in heterochromatic photometry, observers whose eyes may have quite similar characteristics sometimes secure markedly different results, due to the fact that they form different concepts of the appearance which two illuminated surfaces must assume when they are balanced. Usually, an observer forms a concept and adheres to such concept until persuaded that it is improper. This is a matter of memory, tradition, and, sometimes, of external influence. It is common experience that observers who work together in photometry tend to form similar concepts and to agree in their observations under all conditions. Sometimes the concept agreed upon by such observers is the probable correct concept reached as a consensus of opinion. On the other hand it may be the concept of one observer which another observer has been influenced, unconsciously, to accept.

* Ives. *Philosophical Magazine*, December, 1912.

**259. Heterochromatic photometry.** No final determination of the relative illuminating power of lights of different colors has been made. It seems probable that there cannot be any one factor to express this relation because the illuminating power of light of different colors depends, first, upon the intensity at which it is employed and second, upon the purpose for which it is employed. Conditions are ripe, however, for the establishment of arbitrary standards of light of different colors to serve for purposes of heterochromatic photometry. Much work is being done on the subject and reliable standards representing the best assignments of values which have been made will shortly be available. With such standards, consisting either of sources yielding light of various colors or of color filters for modifying the light of a given source, heterochromatic photometry is reduced to the comparison of lights of similar colors, under which conditions the ocular characteristics affecting the problem may be largely ignored.

## STANDARDS OF LUMINOUS INTENSITY

**260. Primary standards now in use.** All primary standards which are employed in practical photometry are flame standards. Flame standards are esteemed rather highly in the gas industry because their candle-power is considered to vary more or less as does the illuminating gas flame with changes in atmospheric conditions. Flame standards include the Hefner lamp, the Pentane lamp, the Carcel lamp and candles. All are capable of yielding accurate results when employed with strict regard for their limitations. The material of combustion must be carefully selected in accordance with strict specifications. The construction must be accurate; good ventilation and freedom from drafts is essential; accurate adjustments and corrections for variations from standard atmospheric conditions are fundamentally important. For detailed description see any text-book on photometry.

**261. Proposed primary standards.** The need for a primary standard of light which shall have a definite value and be absolutely reproducible has led to a number of interesting proposals. Without referring to a number of proposals which have been given a trial, without attaining sufficient sucess to warrant their adoption, it may be said that there are two recent proposals of considerable merit. Steinmets* has suggested that the red, green and blue line radiation of the mercury arc, aggregating one watt, be adopted as a standard of light. Ives† has recommended one watt radiated in energy of maximum luminosity. Both suggestions depend for successful application upon the accurate measurement of radiant energy, and Ives' suggestion involves further the accurate transfer from green to white light through heterochromatic photometry.

**262. International candle and its equivalents.** An important step toward international agreement upon a unit of light was taken through the cooperation of the Illuminating Engineering Society and the Bureau of Standards in 1909. While the Hefner lamp is the official unit of light in Germany, yet the simple relation 1 Hefner = 0.9 international candle was agreed upon as the result of the same international cooperation. The following relations now hold: 1 international candle = 1 Pentane candle = 1 Bougie decimale = 1.11 Hefner unit = 0.104 Carcel unit.

**263. Representative standards.** Seasoned incandescent lamps calibrated in international candles and held in the custody of the Government laboratories in England, France and the United States are for all practical purposes the official standards of light in these countries. Accurately calibrated lamps derived from these standards may be procured from the Bureau of Standards and from testing laboratories for use as reference standards.

**264. Reference standards.** It is customary in important photometric work to procure a number of reference standards calibrated in international candles and to use these occasionally for the verification of other standards which are in daily use and which are known as working standards. These in turn are used for the occasional calibration of comparison standards which are burned continuously in a photometer. All electric incandescent lamp standards have a limited life; hence lamps which are used for continuous

* Transactions A. I. E. E., 1908, p. 1319.
† Transactions Illg. Eng. Soc., 1912, p. 376.

Digitized by Google

comparison purposes must be verified occasionally and the repeated use of the working standards employed in such verifications in turn limits their period of constancy. A complete range of reference standards and working standards is important if comparison standards are to be relied upon for accuracy.

## PHOTOMETERS AND PHOTOMETRIC APPARATUS

**265. Physical or non-ocular photometers.** In the measurement of radiant energy there are employed, at various times, the thermopile, the radiomeater, and the bolometer. These are affected by radiation of various wave lengths in several characteristic ways, and, for some classes of physical investigation, have very important uses. The photo-electric cell, the selenium cell, and the photographic plate also have been investigated with a view to employment as substitutes for the eye in conjunction with a photometric device. In addition to characteristics which impose serious limitations to their use for practical work, these devices are open to the further objection that radiation within the visible spectrum does not affect them in the same proportions as it does the human eye. Their sensibility characteristics do not conform to the luminosity curve of the human eye. The photoelectric cell, for example, is most sensitive in the region of 0.44$\mu$ in the violet and of the spectrum; the selenium cell, on the other hand, is most sensitive to radiation in the region of 0.7$\mu$, which is in the orange-red region of the spectrum. It is possible to correct these devices by employing color screens of such characteristics as to alter the sensibility curve to the desired extent. It is understood that those who are engaged in the study of these devices feel encouraged to hope that they may yet prove their value in some classes of photometric work. Up to the present time, however, they have been of scientific interest rather than of utility, in so far as ordinary photometry is concerned.

**266. Photometric devices—ocular.** It is a characteristic of the human eye, termed "**induction**" that a uniform dark surface placed next a lighter surface appears darker in the region immediately adjacent to the lighter surface than it does in the region farther removed. It follows that in bringing two surfaces to equivalent brightness, the contrast will appear more marked if the surfaces can be brought into close juxtaposition, and, if the contrast is more marked, equivalency can be established with greater

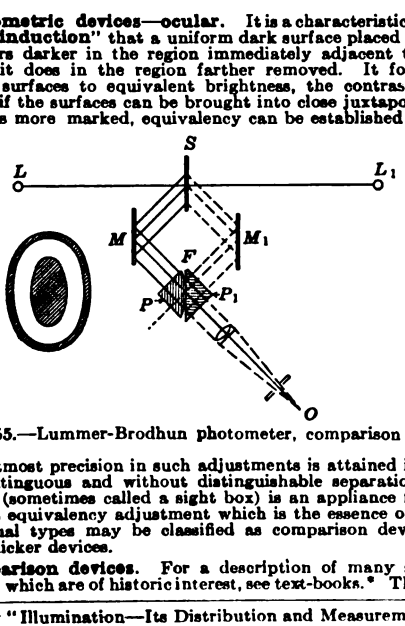

FIG. 55.—Lummer-Brodhun photometer, comparison type.

accuracy. Utmost precision in such adjustments is attained if the surfaces are made contiguous and without distinguishable separation. A photometric device (sometimes called a sight box) is an appliance for promoting the brightness equivalency adjustment which is the essence of photometry. The more usual types may be classified as comparison devices, contrast devices, and flicker devices.

**267. Comparison devices.** For a description of many simple photometric devices which are of historic interest, see text-books.* The comparison

* Especially "Illumination—Its Distribution and Measurement," Trotter.

Digitized by Google

device in most general use at the present time is the simple Lummer-Brodhun cube, which is illustrated in Fig. 55. Light from lamp, $L$, falls upon one side of white plain surface, $S$, and is in part reflected through mirror, $M$, and that part of the two prisms, $P$ and $P_1$, which are in optical contact, to the eye, $O$. Light from the other lamp, $L_1$, falls upon the other side of $S$, is reflected from the mirror $M_1$, to the prism, $P_1$. That part of it which falls upon the part of the prism which is in optical contact with prism $P$, passes through $P$ and is absorbed, while that which falls upon the remainder of the hypothenuse face of $P_1$, is reflected to the eye $O$. Portions of the two surfaces of $S$ are therefore brought into juxtaposition, as indicated in the diagram, and without perceptible line of separation. This form of photometric device is excellent where rapid settings are desired, but is not quite equal for precision work, to the Lummer-Brodhun contrast device.

**268. The Lummer-Brodhun contrast prism** is employed in the same manner as the comparison prism illustrated in Fig. 55. Its construction is different, however, as illustrated by the plan in Fig. 56. The hypothenuse face of one prism is ground away in three places, as indicated, and the alternate halves of the outer faces of the two prisms are covered by thin glass plates, $G$ and $G_1$, which absorb 7 or 8 per cent. of the light which passes through them. The photometric field appears as illustrated in Fig. 56, the light from one side of photometric surface $S$ being represented on the left of

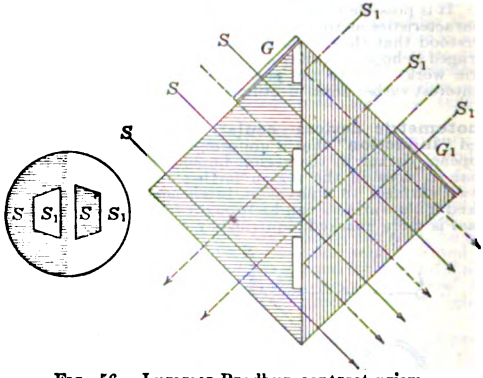

FIG. 56.—Lummer-Brodhun contrast prism.

the diagram and by the trapezoid located in the right half of the field, the latter being 7 or 8 per cent. less bright than the other half of the field. Similarly, the light from the other photometric surface, $S_1$, is represented by the semicircle in the right of the figure and by the trapezoid in the left half of the figure, the latter again being 7 or 8 per cent. less bright. With the contrast cube in proper adjustment and of proper optical characteristics, a photometric balance should bring to equivalent brightness trapezoids, $S$ and $S_1$, and also semicircle $S$ and $S_1$; in addition, the contrast between trapezoid $S_1$ and semicircle $S$ should equal the contrast between trapezoid $S$ and semicircle $S_1$. Devices of this type have highest known sensibility for photometry where no considerable color difference is involved.

**269. Bunsen contrast photometer.** In the Bunsen photometer a translucent screen normal to the photometric axis is rendered of higher translucency at the centre, and the appearance of the opposite surfaces when illuminated by the two lamps between which it is located, is observed through mirrors placed about 140 deg. from one another, as illustrated in Fig. 57. The greater translucency of the centre of the screen may be made by the application of hot paraffin, or, as in the Leeson disc, may be accomplished by cutting a round or star-shaped hole in the disc itself and pasting thin rice paper over both surfaces. Care and skill in the construction of the

Digitized by Google

disc are essential to precision of operation. As in the Lummer-Brodhun contrast photometer, the Bunsen photometer presents to view two contrast fields. If properly constructed with mirrors of equal absorbing power, a condition of balance should bring equality of brightness and equality of contrast.

The Bunsen photometer is preferred by some for routine lamp testing where highest precision in individual measurements is not so important as good maintenance of accuracy throughout the day's work. It is inferior to the Lummer-Brodhun photometer in sensitiveness at low intensities. It is somewhat easier to make settings with the Bunsen photometer than with the Lummer-Brodhun photometer in comparison of lights of markedly different colors for the reason that the illumination of each surface of the disc is due in part to transmitted light from the other surface. Where colors differ, there is a tendency to blend and decrease the color contrast below the actual contrast encountered with a photometer like the Lummer-Brodhun, where the lights are not mixed.

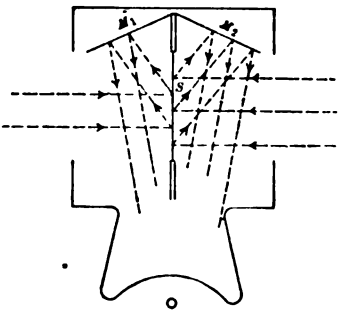

FIG. 57.—Bunsen photometer.

**270. Flicker photometer.** In flicker photometry the criterion of adjustment is the disappearance of the flicker effect, or rarely, the equality of two flicker effects. The flicker photometer is used as a rule only where lights of markedly different colors are to be compared. Due to persistence of vision, the colors, though markedly different, tend to blend when presented to the eye in rapid alternation, and the color differences cease to be perceptible, while differences in brightness of the two surfaces are still visible. It is thus possible to make comparisons of markedly different lights with much less difficulty than when the equality-of-brightness method is employed, and different observers are much more likely to secure similar results, because the criterion rests upon a physiological effect and leaves room for less difference of opinion or less variation of concept than does the equality-of-brightness method. Ives, who has made the most recent and extensive investigations of the subject,* has found that with the flicker photometer, blue and green light is adjudged of lower illuminating power when compared at low intensities with red and yellow light. This is a reversal of the Purkinje effect (Par. **255**) which obtains in equality-of-brightness measurements at very low intensities. He concludes, as the result of his investigations, that the flicker photometer offers the best means of dealing with heterochromatic photometry, but its use should be limited by specifying a standard intensity at which comparison shall be made, a standard visual angle for the photometric field, and observers who are free from peculiarities of color vision. Incidentally, a similar prescription applied to any kind of photometry would do much toward standardization. Ultimately, heterochromatic photometry must be based upon the illuminating power as judged by some such criterion as equality of brightness or power to reveal detail. The disappearance of flicker cannot be considered as an ultimate criterion. However, a flicker photometer once verified and accepted in a given form as a reliable device for heterochromatic photometry, should prove very useful in that class of work because of the readiness with which settings can be made.

**271. Forms of flicker photometer.** Rood† devised the first flicker photometer, which consisted of a wedge, the two faces of which formed the photometric surfaces, which were viewed alternately through a revolving lens. The Whitman photometer is provided with a wheel, portions of whose rim are inclined in opposite directions. As the wheel revolves, it

*Philosophical Magazine*, November, 1912.
† Science, Vol. VII, p. 757.

Digitized by Google

presents to the eye photometric surfaces illuminated in turn by each of the sources under comparison. The Simmance-Abady photometer is similar, but differs in that alternation of the inclination of the rim of the wheel is gradual rather than abrupt. The Schmidt and Haensch flicker photometer is a refinement of the original Rood photometer. The optical construction is such that both surfaces are continuously observed, one surface appearing first as the centre and then as the outer ring of the photometric field as illustrated in Fig. 58. Wild† has devised a form of flicker photometer in which a disc having two different degrees of translucency is rotated while its opposite sides are viewed much as in a Bunsen photometer. Setting with this photometer is made by adjusting for equality of degree of flicker instead of disappearance of flicker.

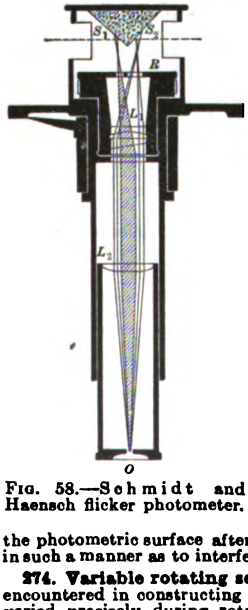

FIG. 58.—Schmidt and Haensch flicker photometer.

**272. Means of changing intensity of light for photometric adjustment.** The principal methods of adjustment of the intensity of illumination upon a photometric surface are variable distance, variable inclination of the surface, variable rotating sector disc, variable diaphragms, polarising devices.

**273. Variable distance.** This adjustment may be accomplished by moving the photometric device between fixed lamps; by fixing the photometric device and moving the comparison lamp; or by joining the photometric device with the comparison lamp and moving both as a unit. The first-mentioned method is that ordinarily employed in commercial photometry of incandescent lamps. The moving comparison lamp is often used in portable photometers and in tests of lighting auxiliaries where it is desired to maintain a fixed distance between the photometer and the light source under test. The movement of the photometric device and the comparison lamp as a unit is sometimes employed in precision photometry where it is desirable to maintain a fixed intensity of illumination upon the photometric surface. In all applications of the variable-distance method of adjustment, it is necessary to keep in mind the limitations of the inverse-square law (Par. **253**) and to guard carefully against errors due to light reaching the photometric surface after being reflected or refracted from other surfaces in such a manner as to interfere with adherence to the inverse-square law.

**274. Variable rotating sector disc.** Serious mechanical difficulties are encountered in constructing a rotating sector disc whose apertures may be varied precisely during rotation. Even if such a device is constructed successfully, it is inherently of low precision in the smaller aperture adjustments where a slight angular adjustment error may involve a large error in the total percentage of light transmitted. One of the interesting applications of this idea is embodied in the Beckstein photometer (Par. **284**) in which the beam of light is rotated about the centre of a stationary sector disc whose angular openings are adjusted as desired.

**275. Variable diaphragms.** Unlike the variable-distance method and the variable rotating sector disc method, the variable diaphragm method is dependent exclusively upon empiric calibration. However, when used in conjunction with a uniformly bright surface, as a diffusing surface or lens, it is a very useful device, and capable of very accurate calibration. Its principal use in commerical photometry is in portable photometers.

**276. Methods of employing photometric apparatus.** The photometric devices which have been described may be used upon bars for the measurement of candle-power in one direction, or with integrating devices for the measurement of total flux, or in portable photometers. In all such

† *Illuminating Engineer*, London, Vol. I, p. 825.

Digitized by Google

applications, any of the methods of varying the intensity which have been described, may be employed. The principles are the same and the applications differ only in accordance with the dictates of convenience and practicability.

**277. Photometer bars.** In the measurement of horisontal candle-power and in the measurement of distribution of light about a source, it is customary to employ a track upon which carriages supporting lamps or photometric devices, may travel smoothly and easily. The **Reichsanstalt bar** is an approved type which, with various modifications, may be procured from any manufacturer of photometric appliances.

**278. Light-distribution apparatus.** A considerable variety of appliances for facilitating the determination of radial distribution of light, is available. These appliances include the Dibdin photometer; devices employing respectively one mirror, two mirrors and three mirrors; the Matthews photometer, employing a ring of mirrors and apparatus in which the test plate is revolved about the source. For detailed description see text-books on photometry and manufacturers' catalogues. All such appliances are designed to facilitate the determination of the intensity of light at various angles in the vertical plane. Since the inverse-square law does not always apply strictly to light from reflectors at the short distances at which the light is utilized, it is good practice to maintain a fixed distance between the surfaces of the photometric device and the centre of the light source.

## INTEGRATING PHOTOMETERS

**279. General description.** An integrating photometer yields in a single measurement the value of the total flux of light or the mean spherical candle-power of a light source. In general, most such devices, by optical or mechanical means, reduce the intensity of the light, at various angles to the vertical of the light source, in proportion to the area of the zone which the angle bisects, and provide a summation of such reduced intensities for the several angles throughout the vertical plane of the source. The **integrating sphere** intercepts and provides an indication of the total light produced by the source. Perhaps the earliest integrating photometer was **Blondel's lumeter.*** Kennelly† also devised an apparatus for mechanical integration. The instruments of Matthews and Ulbricht, and especially the latter, which are used at the present time are described in text-books.

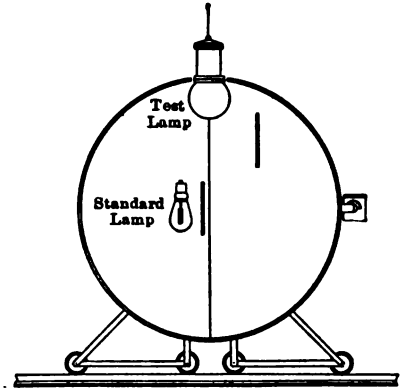

FIG. 59.—Integrating sphere for measuring total lumens or mean spherical candle-power.

**280. Ulbricht integrating sphere.** The integrating sphere devised by Ulbricht has been found to be the most accurate and practical form of integrating photometer. It has been shown that if a light source be located within a hollow sphere having a diffusing inner surface and be screened from a given element of that surface, the illumination of such element, being due entirely to diffuse reflection, will be independent of the location

of the light source and its distribution characteristic. In practice the Ulbricht photometer is a hollow sphere, usually 30 or 80 in. in diameter. It is equipped to facilitate the introduction of the light sources to be measured. It is provided with a suitable screen which is located between the light source and a window which forms one surface of the photometric device. The general arrangement of the sphere is indicated in Fig. 59. The integrating sphere is now recognized as the approved appliance for the determination of total light flux or mean spherical candle-power.

## PORTABLE PHOTOMETERS

**281. Description.** In recent years the use of portable photometers has increased due largely to the development of illuminating engineering which has created a demand for illumination data as determined by measurements in actual installations. Portable photometers involve precisely the same principles as do larger laboratory photometers, and embody, in smaller size, practically the same features of construction. They differ chiefly in that they are enclosed and are provided with a test plate, either attached or detached, which may be used for measuring the total illumination on a plane, irrespective of the direction of incident light. A number of portable photometers have borne or still bear more or less fanciful names, as lumeter, luxometer, illuminometer. All, however, are photometers, and may be subjected to the test of ordinary photometry in the measurement of the candle-power of lamps in a laboratory, in order to determine their accuracy. A few years ago a number of instruments were constructed without due regard for accuracy requirements. Experience has shown, however, that a photometer may be made in a small size and designed for universal application without undue sacrifice of accuracy, and the recent tendency has been to embody in portable photometers all needed precision.

**282. Test plate for illumination measurements.** In the ordinary photometer, judgment is based upon the brightness of two surfaces, one illuminated by a standard lamp and the other by the lamp under test. The brightness of the surfaces is, of course, dependent upon the intensity of the illumination, and the measurement is therefore, one of illumination intensity. However, in most such photometry (integrating photometers excluded) a determination is made of the intensity in one direction only, and the greatest care is exercised to exclude light from any other direction. In the measurement of illumination on the other hand, it is usually desired to measure all light incident upon a given plane, irrespective of its direction. Unlike ordinary photometry, every effort, therefore, is made to secure a proper representation of the light from every direction above the plane studied. Whereas it is a defect of many unidirectional photometers that light other than that from the particular direction desired falls upon the photometric surface, it is a defect of some illumination photometers that all of the light which falls upon the photometric surface does not secure full evaluation. The photometric surface on the test side of the comparison device, is frequently called the "test plate." An ideal test plate has a perfect diffusing surface (Par. 220), the reflected light or the brightness of the surface varying as the cosine of the angle of inclination. The characteristic of such a surface may be indicated, as in Fig. 60, by a circle tangent to the surface. This ideal may be approximated in practice by the light reflected from an opaque plate coated, for example, with magnesia.

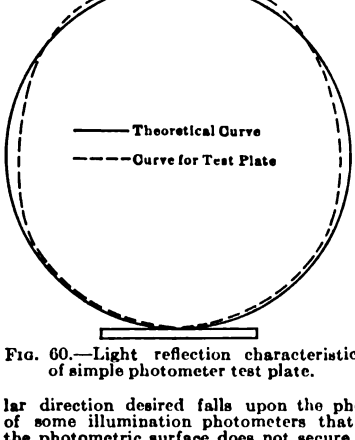

FIG. 60.—Light reflection characteristic of simple photometer test plate.

Digitized by Google

Surfaces which conform most closely to this requirement are, however, not permanent in character. Also, any opaque surface is undesirable for some classes of work because it must be viewed from above, under which conditions it is almost impossible to avoid some obstruction of light by the photometer and the observer. The most satisfactory simple test plate for measurement of illumination under most conditions, consists of a thin milk glass which is free from selective absorption and provided with fine diffusing surfaces, and viewed from below, its brightness being judged by transmitted light. Such plates do not conform exactly to the cosine law of perfect diffusion, but the variation of the best plates from that law is immaterial in most classes of work. The broken line curve in Fig. 60 illustrates the variation of a typical translucent-glass test plate of a simple type.

**283. Weber portable photometer.** The Weber photometer, Fig. 61, was perhaps the first portable photometer embodying most of the features which have been found to be essential to this class of apparatus. In its latest form it consists of a rotating tube containing, at one end, the ocular aperture, $O$, at the centre a Lummer-Brodhun cube, $P$, and at the other end either an attached test plate or a diaphragm for use with a detached test plate, $T$. This tube revolves upon the end of a fixed horizontal tube containing at the other end the comparison lamp, $C$. A translucent glass, $G$, is moved along the axis of this tube, its brightness varying inversely as the square of its distance from the comparison lamp. Looking through the ocular aperture, one sees, as the centre of the photometric field, a portion of either the attached or the detached test plate, and surrounding it a portion of the comparison-lamp glass, the brightness of both being, of course, independent of their distance from the eye. The value corresponding to the location of the comparison-lamp glass, is indicated upon an external scale. This photometer is provided with some absorbing glasses to increase the range, and, in addition, has green and red glasses for insertion in the ocular tube in order to assist in heterochromatic photometry in accordance with a two-color method. This method of color photometry has very limited application.

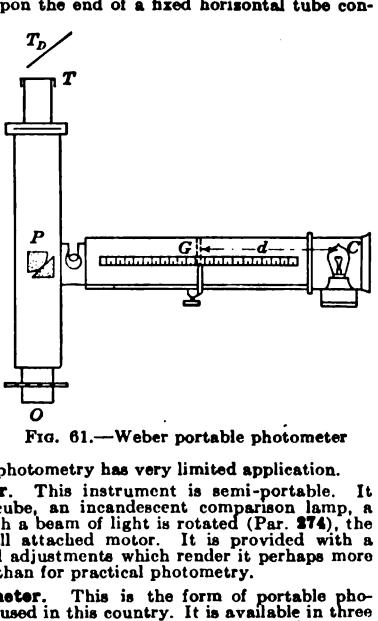

FIG. 61.—Weber portable photometer

**284. Beckstein photometer.** This instrument is semi-portable. It employs a Lummer-Brodhun cube, an incandescent comparison lamp, a variable sector disc, about which a beam of light is rotated (Par. **274**), the prisms being driven by a small attached motor. It is provided with a multiplicity of attachments and adjustments which render it perhaps more suitable for academic purposes than for practical photometry.

**285. Sharp-Millar photometer.** This is the form of portable photometer which is most generally used in this country. It is available in three sizes, respectively 12, 24, and 39 in. long. Fig. 62 shows the essential features as embodied in the smallest size. The photometric device, $P$, consists of a Lummer-Brodhun cube or a microscope glass, mirrored except for a central aperture. Looking through this aperture from ocular aperture $O$, the observer sees either the attached test plate, $T$, which is upon the end of a rotating tube, or the detached test plate, $T_d$. The photometric surface, as seen through this tube, is surrounded in the photometric field by a portion of translucent glass comparison window, $W$. The illumination of window $W$ varies inversely as the square of the distance to moving comparison lamp $C$. The values of a setting is indicated upon a direct-reading translucent scale, illuminated from

Digitized by Google

within by the comparison lamp. A system of baffle screens, $S-1$, etc., protect the window against stray light. The range of the instrument is greatly extended by the use of the absorbing screens, $A$ and $A_1$, which may be rotated about the photometric device, $P$, reducing either the test or the comparison light. For the measurement of candle-power, a part of the rotating tube $R$ which carries the test plate is reversed, thereby providing a protection for the test plate against all extraneous light, permitting it to be illuminated by the light source alone. For the measurement of brightness, the tube $R$ is removed, and any object $B$ is viewed directly through the photometric device. The constancy of the comparison lamp is assured by the employment of a bridge within the photometer, the lamp forming one arm. A sensitive telephone receiver or a galvanometer is used to determine the point of balance of the bridge. When no click is heard upon the interruption of the telephone circuit or when the galvonometer ceases to deflect. the bridge is balanced, and

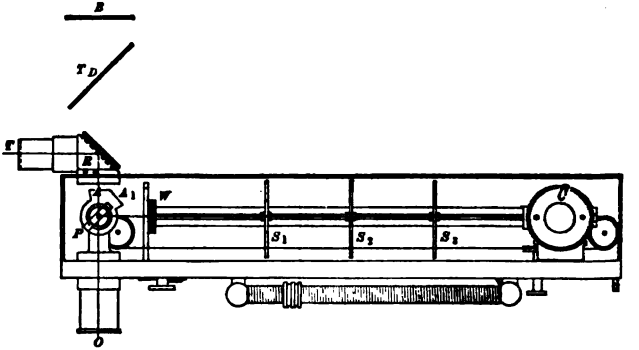

FIG. 62.—Small Sharp-Millar photometer.

the resistance of the comparison lamp is that required by the calibration of the photometer. The resistance characteristic of a tungsten lamp is such as to make this method of control sensitive.

## SPECTROPHOTOMETERS AND COLORIMETERS

**286. Spectrophotometers.** The essential features of a spectrophotometer are indicated in Fig. 63. Some light source is adopted as a basis of comparison and is located at the end of collimator tube $C$, where it is employed to illuminate a diffusing-glass plate. The light source to be tested is permitted to illuminate a similar diffusing-glass plate, which is free from selective absorption and is located at the end of collimator tube $C_1$. A variable-opening slit is located at the end of each collimator tube. At the intersection of the axes of the two collimator tubes, the photometric device, $P$, is located. The light from the two sources which is transmitted and reflected from the photometric device, passes through a dispersing prism, $D$, and into the ocular tube, $O$. This tube may be moved through an arc about the dispersing prism, and so located as to intercept light of any wave length throughout the visible spectrum. At any desired wave length a comparison may be effected, and the light from either source may be varied to secure equality. This adjustment may be made by means of the slits at the end of the collimator tubes or by means of a variable rotating sector disc,* or by varying the distance between the light source and the translucent-glass plate at the end of the collimator tube. In most spectrophotometry it is difficult to obtain sufficient light to make it possible to attain high precision in settings. This is especially the case with measurements made near either end of the spectrum. To an extent not encountered in ordinary photometry,

* Hyde. *Astrophysical Journal*, May, 1912.

Digitized by Google

spectrophotometry is liable to systematic and accidental errors, effects of stray light being notable among the errors of the former class. Results of spectrophotometric tests show relative intensities of light in the several wave lengths throughout the visible spectrum (Par. 27). These are difficult to comprehend and interpret unless one is well versed in such work. Usually it is necessary to refer spectrophotometric differences to differences in color with which one is well acquainted (as that between the Mazda and carbon lamps) in order to form a fairly good concept of magnitude.

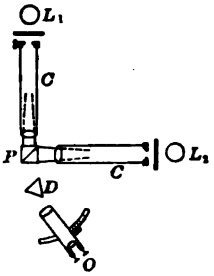

FIG. 63.—Scheme of spectro-photometer.

**287. Colorimeter.** It is generally considered that there are three primary color sensations (Par. 206). In colorimetry, three glasses corresponding to these sensations, respectively red, green and blue, are interposed between the light source to be studied, and a device which mixes the transmitted lights and brings the resultant combined light into juxtaposition with some comparison light for color match. Diaphragms, or variable-width slits, are employed to secure the proper relative proportions of red, green and blue light. In the Ives colorimeter* variable width slits are employed with the colored glasses. The adjustment scale for each slit is calibrated from 0 to 100. With each slit opened to the maximum, the resultant mixture appears white when average daylight is received upon the colored glasses. Color

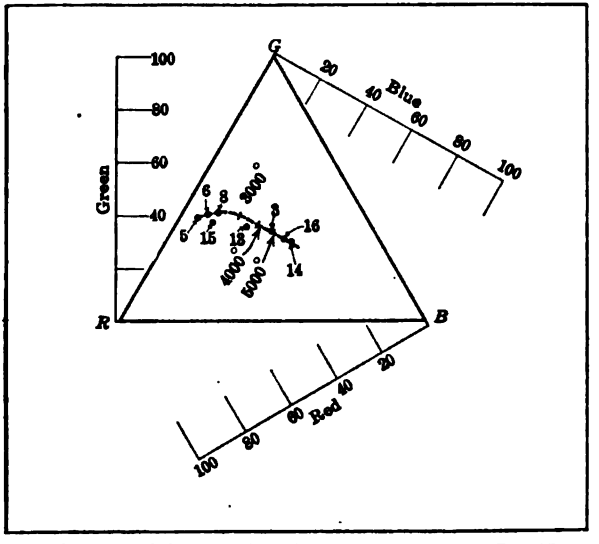

FIG. 64.—Color triangle. For key to numbers see Par. 27.

sensation values are expressed in terms of such maxima. The colorimeter may be employed in the study of light from line spectrum sources, whereas

* Ives. *Journal Franklin Institute*, 1907, p. 164.

Digitized by Google

the spectrophotometer is limited to the study of continuous spectrum or approximately continuous spectrum sources. Sensation values (Par. 27) may be shown with the aid of the Maxwell triangle, Fig. 64.

In this diagram, several illuminants are located as to color, and are shown in comparison with the theoretical black body at several temperatures. The sum of the expressions of color sensations is unity. The sum of the perpendicular distances from the three sides of an equilateral triangle is equal to the altitude of the triangle, which also is taken as unity. Hence, the three color sensations for any illuminant may be indicated by a point on the triangle. The dotted line represents the color of the black body at several temperatures.

## PHOTOMETRIC ADJUNCTS

**288. Standardizing equipments.** An adequate supply of reference standard lamps is important. As far as practicable, these should be of the same types and sizes as the lamps to be tested. For use with a portable photometer there should be a standard lamp box, in which the lamp is enclosed and in which, preferably, there is some device for facilitating the establishment of a standard distance between the lamp and the photometer.

**289. Photometer scales.** In practical photometry, the desirability of having all photometers direct-reading will be obvious. In the case of a fixed photometric device and a moving comparison lamp, the scale is computed in accordance with the simple application of the inverse-square law. A fundamental distance is established at which a given light intensity will be indicated. Distances for other intensities are obtained by the simple application of the inverse-square law, thus:

$$\frac{I}{I_1} = \left(\frac{d_1}{d}\right)^2 \tag{13}$$

In the case of a fixed distance between the test and comparison lamps and a photometric device moving between them, the midway point is assigned the value at which it is desired to maintain the comparison lamp. All other points are determined in accordance with the following equation:

$$d = \frac{D}{\sqrt{\frac{I_c}{I_t}} + 1} \tag{14}$$

where $d$ is the distance between the test lamp and the photometric device, $D$ is the distance between lamps, $I_c$ is candle-power of the comparison lamp and $I_t$ is the candle-power of the test lamp.

**290. Color filters.** Where light sources of a variety of types are to be tested, it is desirable to have an adequate range of color filters which will tend to eliminate most of the problems of heterochromatic photometry. These should have authoritative calibration. Both glass and liquid-solution color filters are being developed on comprehensive scales.

**291. Required accuracy in electrical instruments.** Too much care cannot be devoted to the electrical measuring instruments employed in photometry. To emphasize this it is necessary only to repeat that with Mazda lamps the candle-power error involved in a 1-per cent. voltage error is 4 per cent., and that the corresponding error due to a 1-per cent. ampere error is 6 per cent. Practically all portable voltmeters and ammeters have appreciable scale errors. The extent of such errors should be determined by securing calibration curves for the instruments, and corrections should be made accordingly. Some instruments have temperature coefficients which introduce material errors at times. Also some voltmeters and ammeters are influenced appreciably by external fields. All the precautions taken in electrical measurement should be applied in the use of electrical instruments for photometric work.

**292. Rotating sector discs.** In most laboratory photometry it has been found desirable to use a number of sector discs which are interchangeable on the rotating shaft and which have fixed angular openings, yielding transmission coefficients of respectively 0.1, 0.01, etc. Such employment of the rotating sector disc promotes ultimate accuracy, since, if adjustable discs are used, the opportunity for undetected adjustment errors is considerable, and the adjustment accuracy is low with small angular openings.

Digitized by Google

**293. Absorbing screens** form a valuable adjunct to photometric equipment. Their transmission coefficient, however, is not accurately controllable, and a simple decimal value is therefore rarely obtained. Absorbing screens should transmit without diffusion, and should be free from serious selective absorption. Unfortunately, the usual absorbing screens having low coefficients of transmission, have considerable selective absorption.

**294. Baffle screens.** In practically all photometry it is essential to guard the photometric device against stray light. Opaque screens having suitably proportioned apertures are largely employed for this purpose. A series of these screens, painted black (for most precise work they may be covered with black velvet), is used, for example, on a photometer bar. Where the photometric device or the comparison lamp travels along a track, these screens must be re-located as occasion requires. A most satisfactory method is to so install them that they will be adjusted automatically to the movement of the lamp or photometer carriage. This may be accomplished by mounting them upon lazy tongs, as in several types of commercial lamp-testing photometers, or allowing them to slide upon the track, being pushed in front of the lamp as it approaches the photometric device, and drawn after the lamp by cords or otherwise as it recedes, as in the Sharp-Millar photometer. An alternative to the use of baffle screens is the employment of black velvet to cover all surfaces which may possibly reflect stray light to the photometric device.

**295. Rheostats.** The easy fine adjustment of the current or voltage of a lamp is important to precise work in photometry. Too much care cannot be expended in providing thoroughly satisfactory rheostats for this purpose. Step rheostats are unsatisfactory unless the steps are of such low resistance, in relation to the magnitude of the current, that the change per step is extremely small. A helix of resistance wire, with the coils well insulated, wound upon an insulated tube and mounting a sliding collar having a multiplicity of contact points, is the most generally acceptable form of rheostat for photometric work.

**296. Lamp rotators.** It is usually desired to obtain mean angular intensity of light rather than the light in some particular direction at a given angle. Wherever the nature of the illuminant permits, it is desirable, therefore, to rotate the light source during test, allowing the eye to integrate the intensities to obtain a mean. Most forms of illuminants can be rotated. The speed of rotation of course depends upon the extent to which the light distribution is asymmetrical. If the distribution is approximately symmetrical, a low speed of rotation will suffice. This being the case, it has been found practicable to rotate almost all types of illuminants, including most arc lamps and some forms of gas lamps. The lamp rotator therefore becomes a valuable adjunct in a photometric laboratory. It must be good both mechanically and electrically. As the moving electrical contact required for the supply of the lamp may involve some potential drop, it is customary in the best construction to provide auxiliary moving contacts either of the brush type or of the mercury-cup type, in order to allow the measurement of voltage immediately at the lamp terminals.

## PHOTOMETRIC TESTING

**297. The substitution method of photometry** consists in calibrating a photometer by means of a standard lamp of as nearly as possible the same characteristics as the lamps to be tested, and substituting the lamp to be tested for the standard lamp. A skilled photometrist employing a photometer of exact construction which is perfectly screened and is used with correct electrical instruments for determining the electrical conditions of circuits which are free from potential drop, may obtain correct results in the practical comparison of a test lamp against a standard lamp. Whatever the methods employed, every care should be exercised to secure these favorable conditions for photometry, but if, in spite of care, some conditions exist which are not exactly as they should be, it is quite possible that the substitution method may result in cancelling the effect of such conditions and avoiding erroneous results. By using standard lamps of the same size and type as the lamp to be tested, the substitution method results in correcting both errors of illumination and errors of electrical measurement. If stray light from a 100-candle-power lamp adds 5 per cent. to the illumination of a photometric surface when a moving photometric device is set at 100 on a scale, it will

Digitized by Google

have the same effect when a standard lamp of the same size is used. If then a comparison lamp be calibrated for temporary use by means of the 100-candle-power standard lamp, it will be adjusted 5 per cent. too high. When the 100-candle-power test lamp is measured, the light of the comparison lamp against which it is balanced and the light from the test lamp will both be 5 per cent. too high. The result will be a correct setting. If a voltmeter be employed which has an error of 1 per cent., the effect of the error will be cancelled in the same way if the substitution method is followed. Where considerable photometric work is to be done, the provision of an ample range of reference standard lamps, in order to permit the extensive application of the substitution method, is true economy.

**298. Good practice in measuring illumination.** It is well to be provided with reference standard lamps and a box equipped with baffle screens or black velvet to prevent stray light, in order to produce illumination of known intensities from the standard lamp upon the photometer test plate. It is well to have sufficient standardising equipment of this kind to permit of the verification of the photometer scale at a few points throughout its range and also the verification of photometer absorbing screens. The same equipment may be used in verifying the brightness calibration of the photometer, provided a standard surface of known qualities is obtained with the standard lamps. In such calibration, light of a known intensity is thrown upon the standard surface and the corresponding brightness of the surface is computed (Par. **205**), employing its coefficient of diffuse reflection.

In some illumination work it is sufficient to measure the intensity of illumination at certain points in a room, and it is usually sufficient to measure the brightness of certain objects in the room, as far as data on brightness are concerned. More frequently, however, it is desired to know the average maximum and minimum illumination intensities on certain planes, and to derive the coefficient of utilization (Par. **188**). In such instances it is customary to divide the plane of reference into rectangles, usually providing 20 to 30 such rectangles for the room, or for each bay in the room. A determination of the illumination intensity is then made at the centre of each such rectangle. The mean of such values is usually a fair approximation of the average intensity for the entire plane. Where a detached test plate is employed in the measurement of illumination on a horizontal plane or at any given angle of inclination to the horizontal, it is often desirable to employ an automatic-leveling test plate. In the measurement of horizontal illumination in interiors, a plane 30 or 36 in. above the floor is usually selected. A complete study of a room used, for example, for office purposes, should include the average horizontal illumination on such a plane; the uniformity of such illumination intensities; the brightness of the walls, light sources and other especially prominent objects within view; and measurements of either illumination intensities or brightness on desks to show depth and nature of shadows encountered.

**299. Precautions for avoidance of error.** The following suggestions are commended by experience, and, if followed, are likely to result in the avoidance of some of the most common errors.

Reduce color differences by the use of authoritatively calibrated color filters (Par. **290**).

Follow the substitution method (Par. **297**) as closely as practicable. Provide reference or working-standard lamps of the same size and type as the lamps to be tested.

Consult the characteristics of the light source under test and adapt practice accordingly. For example, allow an arc lamp or a large series incandescent lamp to burn for a short period in order to attain working temperature before making measurements. In testing arc lamps whose values vary through a cycle corresponding with the feeding period, make certain that results are average for such period.

Verify photometer-scale calibration by tests of standard lamps.

Repeat verification at reasonable intervals even though photometer has not been used in interim.

Verify indications of electrical instruments used.

Observe strict cleanliness of apparatus. Dust on transmitting glasses increases coefficient of absorption. Dust on black velvet reflects light.

Verify a few test results by tests upon other apparatus. It is relatively simple for an observer to repeat settings with a given photometer. Make

Digitized by Google

certain that such settings are in accord with results determined by others employing different equipment.

In tests of reflectors make certain that the light source is strictly in accord with the manufacturer's standard of construction, both as to type and dimensions.

Assure correct location of the reflector with reference to the light source. Slight variation in any of these conditions may affect the result materially.

In tests for candle-power and in light-distribution tests, look along the photometric axis from the position of the photometric device to the test lamp and to the comparison lamp. Make certain that all of the light emanating from the light sources in the direction of the photometric device, reaches the photometric surface. Make certain that no other light reaches the surface, that is, avoid stray light.

**300. Sampling.** In sampling for test purposes, whether the samples be lamps, lighting auxiliaries, or illumination installations, it is important that the samples be unquestionably representative of the product which is to be judged by the results of the test. It is also essential that the samples be sufficient in number to guard against the exertion of undue influence upon the final result due to the presence of an eccentric individual among the samples. It is hardly possible to judge intelligently in these matters unless one is thoroughly acquainted with the characteristics of the product which is being sampled. No small part of expertness in testing lies in the successful sampling of the product to be tested. Lamps, reflectors, etc., are not uniform, and very misleading results may follow upon injudicious sampling.

**301. Principles of comparison.** In comparing illuminants it is important to bear in mind first, that some illuminants require more adaptation and suffer in efficiency more in adaptation for a given service than do other illuminants; and, second, that some illuminants deteriorate more largely in efficiency during life than do others. For example, a magnetite arc lamp as equipped is well adapted to street-lighting service, and its efficiency in the condition delivered by the manufacturer is substantially its service efficiency. On the other hand, incandescent lamps may have to be equipped with globe or reflectors or both before application to street-lighting service, and their efficiency as shipped by the manufacturer is materially higher than is their service efficiency. As another example, the candle-power depreciation of a 25-watt Mazda lamp is less during its life than is the candle-power depreciation of a 100-watt Mazda lamp. Conclusions based upon initial laboratory values should be modified where necessary before determining upon relative merit of two different kinds or sizes of illuminants for a given class of service. Likewise, lighting auxiliaries are not always directly comparable on the basis of their initial laboratory values. The deterioration of reflecting surfaces may be rapid. Some surfaces collect and retain dust more largely than do others, and, in consequence, their deterioration of light is greater in a given period.

**302. Discussion of results.** In discussion of test results it is rarely possible to draw unqualified conclusions as to relative merit between appliances or installations which are of more or less the same order of merit. In any test all that is demonstrated is that a sample or a set of samples or an installation has been found, in a given instance, to be superior in certain respects. It is dangerous to draw sweeping conclusions from tests. To do so may mislead when test data are applied to appliances or installations which have not actually been tested. In discussing results of tests and drawing conclusions from tests it is well to be cautious in accepting the basis of measurement as a final indication of value. The candle-power of an incandescent lamp is one direction or in one plane is not necessarily an indication of the illuminating power of the lamp. In the long run, the total light flux or the mean spherical candle-power is most nearly a correct indication, but even this measurement may fail to indicate the real value of an illuminant for a certain class of service. It may be shown that the minimum normal illumination intensities provided by two installations of illuminants for street-lighting service are equal, but this does not demonstrate that the two systems are of equal value. One may deliver twice as much light as the other upon the street. The mean horizontal illumination may be in the long run a reasonably good measure of street-lighting effectiveness, but even this measure may fail to indicate the facts for certain classes of service. In short, tests of illumination should be conducted and conclusions should be drawn from

Digitized by Google

such tests in accordance with the dictates of common sense and good engineering practice.

# SECTION 15

## INDUSTRIAL MOTOR APPLICATIONS
## MACHINE TOOLS

**BY LEON P. ALFORD**

*Editor American Machinist, Member, American Society of Mechanical Engineers*

**1. Definition.** The term "machine tools" cannot be accurately defined. Broadly they are machines used to work and shape metals. A legal definition, taken from the Underwood tariff law, Par. 167, reads as follows: "Machine tool as used in this paragraph shall be held to mean any machine operated by other than hand power which employs a tool working on metal."

**2. The two principal classes** into which they divide are distinguished by the kind of motion of the work or cutting tools. This motion may be either rotating or reciprocating. In the former instance the speed is usually constant throughout each operation, and the energy absorbed is used in overcoming the friction of the machine and in doing useful work in cutting or forming metals. The exceptions are machines that accelerate during the cutting operations, such as squaring-up lathes and lathe-type cutting-off machines. In the second class the power is subject to great fluctuations during a working cycle. For, in addition to the friction losses and useful work done there are large, regular demands for energy with which to retard and accelerate heavy parts of the machine, or the pieces which are being shaped.

**3. The friction losses in rotating machines,** such as lathes, boring mills, drilling machines, milling machines, grinders, and the like vary almost directly as the speed, the gear ratio remaining constant. The loss in the gearing and feeding mechanism comprises the larger part of the friction losses.

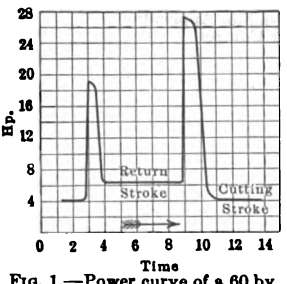

FIG. 1.—Power curve of a 60 by 60-in. planer.

**4. The friction losses in reciprocating machines,** such as planers, shapers, slotters, and the like, are very small in comparison with the losses due to inertia. In fact the inertia losses often exceed the useful work to such an extent as to determine the size of motor (this is especially the case with short-stroke machines). Fig. 1 shows a power curve taken by G. M. Campbell for a 60 × 60 in. × 20 ft. Pond planer. It shows the power input when running light plotted with time. The cutting-stroke speed was 25 ft. per min. (7.6 m. per min.) and the return-stroke speed 60 ft. per min. (18.3 m. per min.).

**5. Group drive and individual drive.** Motor applications to machine tools divide into two classes, group drives and individual drives. It is impossible to lay down a general principle to be followed in the selection of drive for a given case, for there are many modifying factors. Very large machines (those located under a crane) and all machines requiring variable-speed drive are commonly provided with individual motors. Small and medium-sized machines are usually arranged in groups and driven from a line shaft which in turn is driven by a constant-speed motor. If there are a number of reciprocating machines in the group, it is not uncommon to add a fly-wheel to the motor.

Digitized by Google

**6. A comparison of lineshaft and individual-motor drives,*** for machine tools is given in the following table:

| Item | Lineshaft drive | Individual motor drive | Advantage of individual motor |
|---|---|---|---|
| 1. Power consumption. | Constant friction loss in shaft, belts and motor, power for cutting. | Friction loss (motor and tool only) useful power only while working. | Less power required. |
| 2. Speed control. | No. speeds = No. cone pulleys × No. gear ratios. | No. speeds = No. controller points × No. gear ratios. | More speeds possible; time saved in speed adjustments. |
| 3. Reversing. | Clutch and crossed belt. | Reversible controller. | Time saved in reversing. |
| 4. Adjusting tool and work. | Stopping at any definite point very difficult. | Can be started in either direction and stopped at any point. | Time saved in setting up and lining up. |
| 5. Speed adjustment. | Large speed increments between pulley steps. | Small speed increments between controller steps. | Time saved by obtaining proper cutting speed. |
| 6. Size of cut. | Limited by slipping belt; large belts hard to shift. | Limited by strength of tool and size of motor. | Time saved by taking heavier cuts. |
| 7. Time to complete a job. | ..... | ..... | Much less time required as indicated for previous items. |
| 8. Liability to accidents. | Slipping or breaking belt; injury to machine tools, cutting tool or prime mover. | Injury to machine tool, cutting tool or motor. | Much less liability to accident. |
| 9. Checking economy of operations. | Close supervision required, very difficult to locate causes of delay. | Accurate tests possible by means of graphic meter which records automatically all delays and rate of cutting. | Causes of delay and remedies easily located without personal supervision. |
| 10. Flexibility of location. | Location determined by shafting, and changes difficult. | Location determined by sequence of operation changes readily made. | Greater convenience in handling and increased economy of operation; more compact arrangement possible. |

**7. Motors for individual drives** have been tentatively standardized by a committee of the National Machine Tool Builder's Association conferring with a committee of the American Association of Electric Motor Manufacturers. Although the design data were agreed upon in substance early in 1910, the motor manufacturers have failed to use it in the manufacture of their product. An abstract of the report of these committees appears in Par. 8.

* Robbins, Charles. *Trans.* A. S. M. E., Vol. XXXII, page 182.

**8. Standardized specifications for individual-drive motors.**

(a) **Horse power.** Ten sizes are considered necessary for practically all requirements of electric drive for machine tools. These sizes are as follows: 1, 1.5 (for direct current only), 2, 3, 5, 7.5, 10, 15, 20 and 25.

(b) **Voltages** for direct-current motors should be 115 and 230 volts. For alternating-current motors the voltages should be 110 and 220 volts.

(c) **Horse-power ratings.** Where approximately standard load conditions exist, motors are to be given a continuous constant horse-power rating. For variable-speed motors used under intermittent service conditions, the standard 2-hr. continuous-duty rating is to be used for ordinary shop conditions.

(d) **Direct-current motor speeds.** Variable-speed motors are to be standardized for two ranges, namely, 2 to 1, and 3 to 1. The following table includes the recommended speeds for variable-speed direct-current motors.

| Horse power | Speeds | Speeds |
|---|---|---|
| | Ratio 2 : 1 | Ratio 3 : 1 |
| | r.p.m. | r.p.m. |
| 1 | 1,500–750 | 1,500–500 |
| 1½ | 1,500–750 | 1,500–500 |
| 2 | 1,500–750 | 1,500–500 |
| 3 | 1,500–750 | 1,500–500 |
| 5 | 1,200–600 | 1,200–400 |
| 7½ | 1,200–600 | 1,200–400 |
| 10 | 1,200–600 | 1,200–400 |
| 15 | 1,200–600 | 1,200–400 |
| 20 | 900–450 | 900–300 |
| 25 | 900–450 | 900–300 |

(e) **Alternating-current motor speeds.** The following table gives the recommended speeds for polyphase 60-cycle alternating-current motors.

| Horse power | Speeds | Horse power | Speeds |
|---|---|---|---|
| 1 | 1,800 and 1,200 | 10 | 1,200 and 600 |
| 2 | 1,200 | 15 | 900 and 600 |
| 3 | 1,200 | 20 | 900 and 600 |
| 5 | 1,200 | 25 | 900 and 600 |
| 7½ | 1,200 and 900 | | |

(f) **Frequency.** In considering constant-speed alternating-current motors 60 cycles is to be used as the basis.

**9. Methods of applying motors to machine tools.***

(a) **Bench lathes** should be driven from a countershaft attached to the bench and driven in its turn by motor. Any type of motor may be used except the series-wound or the heavily compounded motors. It is essential to locate the machine in the most advantageous manner without regard to the position of the shaft.

(b) **Speed lathes** should be driven from a self-supported countershaft or by a direct-connected motor. In the latter case a variable-speed machine is to be preferred.

(c) **Engine lathes.** For these both variable-speed and constant-speed motors are used although engine lathes are usually group-driven. Where individual motors are used, each is placed on a bracket attached to the lathe, and connected to it with a geared or chain drive.

(d) **Heavy engine lathes, forging lathes, etc.,** should be driven by direct-connected direct-current motors. The position of the motor should be low to reduce vibrations in its support. The output of these lathes may be increased from 20 to 25 per cent. by motor drive.

* DeLeeuw, A. L. *Trans.* A. S. M. E., Vol. XXXII, page 137.

Digitized by Google

(e) **Axle lathes, wheel lathes and driving-wheel lathes** should be driven by direct-current motors.

(f) **Chucking lathes** usually are not motor-driven. If motors are used they should be of variable speed.

(g) **Automatic screw machines** in small sizes should be group-driven; in the larger sizes they should preferably be driven by variable-speed motors.

(h) **Sensitive drilling machines** in general should not be motor-driven. However, if machine is placed in an isolated location, a motor may be directly applied to the machine itself or the machine may be driven through a countershaft, from a motor on the floor.

(i) **Vertical and radial drilling machines** are usually group-driven unless they are isolated. If such machines are motor-driven, the variable-speed type should be selected. The motor may be direct connected to the machine itself or set up to drive the machine countershaft.

(j) **Boring machines**, if used for specialised work, are preferably belt-driven. If used for a variety of operations, a variable-speed motor is desirable.

(k) **Grinders** should be driven by constant-speed motors belted to the grinder countershafts.

(l) **Planers**, particularly those of small size, if located under a crane, should be driven by variable-speed motors. A recent development is the reversing-motor planer drive which is now being extensively tested, and promises to prove successful.

(m) **Shapers, slotters, etc.**, should usually be group-driven.

(n) **Knee and column-type milling machines** in the large sizes should be driven by variable-speed motors, especially if used in "gang" operations.

(o) **Planer-type milling machines** should be motor driven. Either the constant-speed or the variable-speed types will prove satisfactory.

**10. Values of horse power required to cut metal***

Lathe-type tools

| Material | Horse power required to remove 1 cu. in. per min. |
|---|---|
| Brass and similar alloys | 0.2 to 0.3 |
| Cast iron | 0.3 to 0.5 |
| Wrought iron | 0.6 |
| Mild steel (0.30–0.40 per cent. carbon) | 1.00 to 1.25 |
| Hard steel (0.50 per cent. carbon) | 1.5 |
| Very hard tire steel | |

Drills

| Material | Horse power required to remove 1 cu. in. per min. |
|---|---|
| Brass and similar alloys | 0.4 to 0.6 |
| Cast iron | 0.6 to 1.0 |
| Wrought iron | 1.2 |
| Mild steel (0.30–0.40 per cent. carbon) | 2.0 to 2.5 |
| Hard steel (0.50 per cent. carbon) | 3.0 |
| Very hard tire steel | |

**11. Determination of horse power required for machines under group drive.** A table of power values for machine tools is given in Par. **12.** These values are the result of tests made by the author under actual shop conditions, and apply to small and medium-sized machines only. The output of the factory where the investigation was made was light automatic machines. The parts operated on during the tests were iron and steel castings, drop forgings and bar stock. Manufacturing conditions were highly developed, and the degree of finish allowed was small. Because of these conditions the power values are still useful although they were obtained before the common use of high-speed steel in cutting tools. The values

* Robbins, Charles. *Trans.* A. S. M. E., Vol. XXXII, pp. 199 to 209

Digitized by Google

have been checked by their application to a number of factories whose tot power load was known. This showed that, for a group of machines, the su of the power values given in the table is about 20 per cent. higher than t average working load. This is because of the intermittent service of too for various reasons, or the departmental slip.

**13. The horse-power values for individually driven machine tools** given in the following paragraphs are recommended by the Westinghouse Electric and Manufacturing Co. As these values are based on average practice, they may be decreased for very light work and must often be increased for very heavy work. The recommended type of motor is indicated by the symbols A, B, C. (A) Adjustable-speed, shunt-wound, direct-current motors are used wherever a number of speeds are essential. (B) Constant-speed, shunt-wound direct-current motors are used where the speeds are attainable by a gear box or cone-pulley arrangement or where only one speed is required. (C) Squirrel-cage induction motors are used where direct current is not available. A gear box or cone-pulley arrangement must be used to obtain different speeds.

**14. Boring machines**

| Motor A, B or C (Par. 13) | | |
|---|---|---|
| Diameter of spindle (in.) | Maximum boring diameter (in.) | Horse power |
| 4 | 20 | 7½ |
| 6 | 30 | 10 |
| 8 | 40 | 15 |

Digitized by Google

### 15. Bolt and nut machinery

| Style | Size (in.) | Horse power |
|---|---|---|
| **(a) Bolt cutters—motor A, B or C (Par. 13)** | | |
| Single | 1, 1½, 1¾ | 1 to 2 |
| | 1¾, 2 | 2 to 3 |
| | 2½, 3½ | 3 to 5 |
| | 4, 6 | 5 to 7½ |
| Double | 1, 1½ | 2 to 3 |
| | 2, 2½ | 3 to 5 |
| Triple | 1, 1½, 2 | 3 to 7½ |
| **(b) Bolt pointers—motor B or C** | | |
| | 1¼, 2½ | 1 to 2 |
| **(c) Nut tappers—motor A, B or C** | | |
| Four-spindle | 1, 2 | 3 |
| Six-spindle | 2 | 3 |
| Ten-spindle | 2 | 5 |
| **(d) Nut facer—motor B or C** | | |
| | 1, 2 | 2 to 3 |

### 16. Bolt heading, upsetting and forging machines

| Size (in.) | Horse power |
|---|---|
| Motor A,* B† or C‡ (Par. 13) | |
| ¾ to 1¼ | 5 to 7½ |
| 1½ to 2 | 10 to 15 |
| 2½ to 3 | 20 to 25 |
| 4 to 6 | 30 to 40 |

### 17. Boring and turning mills

| Size (in.) | Horse power | |
|---|---|---|
| Motor A, B or C (Par. 13) | | |
| | Average work | Heavy work |
| 37 to 42 | 5 to 7½ | 7½ to 10 |
| 50 | 7½ | 7½ to 10 |
| 60 to 84 | 7½ to 10 | 10 to 15 |
| Size (ft.) | | |
| 7 to 9 | 10 to 15 | |
| 10 to 12 | 10 to 15 | 30 to 40 |
| 14 to 16 | 15 to 20 | |
| 16 to 25 | 20 to 25 | |

* Speed variation is sometimes desired when different sizes of bolts are headed on the same machine.

† Compound-wound, direct-current motor.

‡ Wound secondary or squirrel-cage motor with approximately 10 per cent. slip.

Digitized by Google

### 18. Bulldozers

| Motor B* or C† (Par. 13) | | |
|---|---|---|
| Width (in.) | Head movement (in.) | Horse power |
| 29 | 14 | 5 |
| 34 | 16 | 7½ |
| 39 | 16 | 10 |
| 45 | 18 | 15 |
| 63 | 20 | 20 |

### 19. Drilling machines

| Motor A, B or C (Par. 13) | |
|---|---|
| (a) Sensitive machines up to ½ in. drill capacity | 0.25 to 0.75 horse pow |
| (b) Vertical drilling machines | |
| Size (in.) | Horse power |
| 12 to 20 | 1 |
| 24 to 28 | 2 |
| 30 to 32 | 3 |
| 36 to 40 | 5 |
| 50 to 60 | 5 to 7½ |

(c) Radial drilling machines

| Length of arm—ft. | Horse power | |
|---|---|---|
| | Average conditions | Heavy |
| 3 | 1 to 2 | 3 |
| 4 | 2 to 3 | 5 to 7½ |
| 5, 6 and 7 | 3 to 5 | 5 to 7½ |
| 8, 9 and 10 | 5 to 7½ | 7½ to 10 |

### 20. Drilling, boring and milling machines

| Motor A, B or C (Par. 13) | |
|---|---|
| Size of spindle (in.) | Horse power for single spindle |
| 3½ to 4½ | 5 to 7½ |
| 4½ to 5½ | 7½ to 10 |
| 5½ to 6½ | 10 to 15 |

For machines with double spindles use motors of double the horse power given.

* Compound wound motor.

† Wound secondary or squirrel-cage motor with approximately 10 per cent. slip.

Digitized by Google

### 21. Drilling machines—multiple spindle

| Motor A, B or C (Par. 13) | | |
|---|---|---|
| Size of drills (in.) | No. of spindles | Horse power |
| 1/32 to 1/4 | 6 to 10 | 3 |
| 1/16 to 3/8 | 10 | 5 |
| 1/8 to 1/2 | 10 | 7½ |
| 1/4 to 3/4 | 10 | 10 |
| 1/2 to 1 | 10 | 10 to 15 |
| 2 | 4 | 7½ |
| 2 | 6 | 10 |
| 2 | 8 | 15 |

### 22. Gear cutters

| Motor A, B or C (Par. 13) | |
|---|---|
| Size (in.) | Horse power |
| 36×9 | 2 to 3 |
| 48×10 | 3 to 5 |
| 30×12 | 5 to 7½ |
| 60×12 | 5 to 7½ |
| 72×14 | 7½ to 10 |
| 64×20 | 10 to 15 |

### 23. Grinders

(a) Tool, snagging, etc.—motor B or C (Par. 13)

| Wheels | | |
|---|---|---|
| No. | Diameter wheel (in.) | Horse power |
| 2 | 6 | ½ to 1 |
| 2 | 10 | 2 |
| 2 | 12 | 3 |
| 2 | 18 | 5 to 7½ |
| 2 | 24 | 7½ to 10 |
| 2 | 26 | 7½ to 10 |

(b) Cylindrical—motor A, B or C (Par. 13)

| Dia. wheel (in.) | Length work (in.) | Horse power | |
|---|---|---|---|
| | | Average work | Heavy work |
| 10 | 50 | 5 | 7½ |
| 10 | 72 | 5 | 7½ |
| 10 | 96 | 5 | 7½ |
| 10 | 120 | 5 | 7½ |
| 14 | 72 | 10 | 15 |
| 18 | 120 | 10 | 15 |
| 18 | 144 | 10 | 15 |
| 18 | 168 | 10 | 15 |

Digitized by Google

**23. Grinders.**—*Continued*
Miscellaneous—motor B or C (Par. 13)

| | Horse power |
|---|---|
| Wet tool grinder | 2 to 3 |
| Flexible swinging, grinding and polishing machine | 3 |
| Angle-cock grinder | 3 |
| Piston-rod grinder | 3 |
| Twist-drill grinder | 2 |
| Automatic tool grinder | 3 to 5 |

**24. Hammers**

| Motor B* or C† (Par. 13) | |
|---|---|
| Size (lb.) | Horse power |
| 15 to 75 | ½ to 5 |
| 100 to 200 | 5 to 7½ |

Drop-hammers require approximately 1 h.p. for every 100-lb. weight of hammer head.

**25. Lathes**—motor A, B or C (Par. 13)
(a) Engine lathes

| | Horse power | |
|---|---|---|
| Swing (in.) | Average | Heavy |
| 12 | ½ | 2 |
| 14 | ¾ to 1 | 2 to 3 |
| 16 | 1 to 2 | 2 to 3 |
| 18 | 2 to 3 | 3 to 5 |
| 20 to 22 | 3 | 7½ to 10 |
| 24 to 27 | 5 | 7½ to 10 |
| 30 | 5 to 7½ | 7½ to 10 |
| 32 to 36 | 7½ to 10 | 10 to 15 |
| 38 to 42 | 10 to 15 | 15 to 20 |
| 48 to 54 | 15 to 20 | 20 to 25 |
| 60 to 84 | 20 to 25 | 25 to 30 |

(b) Axle lathes

| | | Horse power |
|---|---|---|
| Single | | 5, 7½, 10 |
| Double | | 10, 15, 20 |

(c) Wheel lathes

| Size (in.) | Horse power | |
|---|---|---|
| | Main-drive motor | Tail-stock motor‡ |
| 48 | 15 to 20 | 5 |
| 51 to 60 | 15 to 20 | 5 |
| 79 to 84 | 25 to 30 | 5 |
| 90 | 30 to 40 | 5 to 7½ |
| 100 | 40 to 50 | 5 to 7½ |

* Compound-wound motor.
† Wound secondary squirrel-cage motor with approximately 10 per cent. slip.
‡ Standard machine-tool traverse motor.

### 26. Milling machines

Motor A, B or C (Par. 13)

Vertical slab milling machines

| Width of work (in.) | Horse power |
|---|---|
| 24 | 7½ |
| 32 to 36 | 10 |
| 42 | 15 |

Vertical milling machines

| Height under work (in.) | Horse power |
|---|---|
| 12 | 5 |
| 14 | 7½ |
| 18 | 10 |
| 20 | 15 |
| 24 | 20 |

Plain milling machines

| Table feed (in.) | Cross feed (in.) | Vertical feed (in.) | Horse power |
|---|---|---|---|
| 34 | 10 | 20 | 7½ |
| 42 | 12 | 20 | 10 |
| 50 | 12 | 21 | 15 |

Universal milling machines

| Machine no. | Horse power |
|---|---|
| 1 | 1 to 2 |
| 1½ | 1 to 2 |
| 2 | 3 to 5 |
| 3 | 5 to 7½ |
| 4 | 7½ to 10 |
| 5 | 10 to 15 |

Horizontal slab milling machines

| Width between housings | Horse power | |
|---|---|---|
| (In.) | Average | Heavy |
| 24 | 7½ to 10 | 10 to 15 |
| 30 | 7½ to 10 | 10 to 15 |
| 36 | 10 to 15 | 20 to 25 |
| 60 | 25 | 50 to 60 |
| 72 | 25 | 75 |

**27. Pipe threading and cutting off machines**

| Motor A, B or C (Par. 18) | |
|---|---|
| Size pipe (in.) | Horse power |
| ¼ to 2 | 2 |
| ⅜ to 3 | 3 |
| 1 to 4 | 3 |
| 1¼ to 6 | 3 to 5 |
| 2 to 8 | 3 to 5 |
| 3 to 10 | 5 |
| 4 to 12 | 5 |
| 8 to 18 | 7½ |
| 24 | 10 |

**28. Planers**

| Motor B* or C (Par. 18) | | |
|---|---|---|
| Width (in.) | Distance under rail (in.) | Horse power |
| 22 | 22 | 3 |
| 24 | 24 | 3 to 5 |
| 27 | 27 | 3 to 5 |
| 30 | 30 | 5 to 7½ |
| 36 | 36 | 10 to 15 |
| 42 | 42 | 15 to 20 |
| 48 | 48 | 15 to 20 |
| 54 | 54 | 20 to 25 |
| 60 | 60 | 20 to 25 |
| 72 | 72 | 25 to 30 |
| 84 | 84 | 30 |
| 100 | 100 | 40 |

Normal length of bed in feet is about ¼ the width in inches.

**29. Rotary planers**

| Motor A, B or C (Par. 18) | |
|---|---|
| Dia. of cutter (in.) | Horse power |
| 24 | 5 |
| 30 | 7½ |
| 36 to 42 | 10 |
| 48 to 54 | 15 |
| 60 | 20 |
| 72 | 25 |
| 84 | 30 |
| 96 to 100 | 40 |

**30. Polishing and buffing machines**

| Motor B or C (Par. 18) | | |
|---|---|---|
| Wheels | | Horse power |
| No. | Diameter (in.) | |
| 2 | 6 | ¼ to ½ |
| 2 | 10 | 1 to 2 |
| 2 | 12 | 2 to 3 |
| 2 | 14 | 3 to 5 |

For brass tubing use double the above horse-power values.

* Compound-wound motor.

**39. The direct-connected adjustable-speed reversing motor** is the most recent development in motors for machine tools. It has been applied to planers, slotters, key-seaters, wire and tube drawing machines and large boring mills. Its advantages lie in increased production and saving of power. Figs. 2 to 6, inclusive show five planer drives.* These curves are drawn to the same scale and show the power required to drive "light" and with normal cuts, see Par. **38**.

**40. Power required by portable armature drills**

## WOOD-WORKING MACHINERY

**BY CHESTER W. DRAKE**

*Commercial Engineer, Westinghouse Electric & Manufacturing Co., Associate, American Institute of Electrical Engineers*

### SAWING

**41. Band saws** are replacing circular saws in most saw mills, since the saving they effect in the kerf much more than offsets their higher first cost, labor and maintenance charges. Band saws having wheels 8 ft., 9 ft. and 10 ft. diameter are in principal use and their power requirements vary widely with the kind and size of logs and the cutting speed.

**42. Type of motor suitable for band saws.** Induction motors, either of the squirrel-cage or wound-rotor type may be used for driving band mills, but special attention to the motor and control characteristics are necessary. The band wheels have a total weight of several tons, and when running at a saw speed of 10,000 ft. per min. have a very large fly-wheel effect. Consequently, a motor is required which has a high starting torque and is able to bring the mill to speed in about a minute. A squirrel-cage motor with a high slip (7 or 8 per cent.) will develop a high torque at starting, and besides this has the additional advantage due to its slip of allowing the band saw to slow down at times of heavy load, and give up some of its stored energy. In this way the load fluctuation on the motor and the system may be considerably reduced. A slip-ring motor gives a high starting torque, but with the secondary short-circuited has a low slip, and consequently the motor is subjected to all the instantaneous peaks of load. A permanent resistance may, however, be connected in the secondary circuit to give any desired slip. An advantage of this method is that the heat thus generated is external to

* Fair, Charles. *American Machinist*, Vol. XXXVIII, page 103.

† These figures include losses in the motor. Careful tests in which the motor losses were separated showed that the power utilized at the drill point varied from 3.13 to 4.1 kw. per lb. of mild steel per min. and from 1.57 to 2.69 kw. per lb. of cast iron per min., the low figures referring to 2-in. holes and the high ones to small holes.
